Terminology and Definitions

Good urogynaecological practice is dependent on the accurate definition of conditions. Any condition can be described in terms of symptoms, signs, and/or urodynamic or non-urodynamic observations. A symptom is the subjective indicator of a disease or change in condition as perceived by the patient and may lead them to seek help. A sign is any abnormality indicative of disease or a health problem, discoverable on examination of the patient; an objective indication of disease or a health problem.

The symptom of incontinence is the complaint of involuntary loss of urine (Abrams et al 2002). However, there are several types of incontinence symptoms. These have been defined by the International Continence Society's Standardization of Terminology Committee and are shown in Box 52.1. This chapter will focus on 'stress' urinary incontinence.

Stress incontinence is a well-recognized and familiar term; however, it can be misinterpreted by patients. Some patients make the assumption that 'stress' refers to their psychological state. In an attempt to reduce this confusion, other terms have been suggested such as 'activity incontinence' or 'urethral sphincter incompetence'.

The sign of stress incontinence is the observation of involuntary leakage from the urethra synchronous with effort or physical exertion, or on sneezing or coughing.

However, the urodynamic observation of stress incontinence is defined as the involuntary leakage of urine during filling cystometry, associated with increased intra-abdominal pressure, in the absence of a detrusor contraction.

The variation in prevalence of women in the population with stress incontinence partly depends on whether the presence of a symptom, sign or urodynamic observation is measured. This makes it difficult to be certain of the true prevalence of stress and other types of incontinence.

Epidemiology

The prevalence of incontinence is defined as the probability of being incontinent within the defined population group at a defined time point. The incidence of incontinence is the probability of developing incontinence during a defined period.

Almost all epidemiological studies of incontinence are cross-sectional and assess prevalence. There is a need for longitudinal studies to assess the risk factors, incidence, remission and impact of preventative strategies.

In the epidemiological assessment of the prevalence of incontinence, it is important to define the population because incontinence has been shown to vary with age and race. The prevalence of incontinence in an institutional elderly care setting is much higher than in a community-dwelling young population. Prevalence estimates for the most inclusive definitions of incontinence (e.g. 'have you ever experienced urinary incontinence') vary greatly from 5% (van Oyen and van Oyen 2002) to 69% (Swithinbank et al 1999); however, most studies fall within the range of 25–45% (Thomas et al 1980, Yarnell et al 1981, Holst and Wilson 1988, Rekers et al 1992, Lara and Nacey 1994, Hannestad et al 2000).

There is evidence that the prevalence varies depending on the methodology of the questionnaire, such as whether the survey was conducted by telephone or post.

Another factor which greatly impacts on the prevalence of urinary incontinence is bothersomeness. Swithinbank et al (1999) demonstrated that although urinary symptoms are common among the female population, they are not always perceived as a problem. Stress incontinence was experienced, at least occasionally, by 60% of the women, but only half of them felt that it was a problem.

There is less variation when studies asked about daily incontinence. Three studies conducted in women under 60

Box 52.1 International Continence Society's (ICS) standardization of terminology

Stress urinary incontinence: involuntary leakage on effort or exertion, or on sneezing or coughing.

Urge urinary incontinence: involuntary urinary leakage accompanied by or immediately preceded by urgency.

Mixed urinary incontinence: involuntary urinary leakage associated with urgency and also with effort or exertion, or on sneezing or coughing.

Enuresis: any involuntary loss of urine. If it is used to denote incontinence during sleep, it should be qualified by the adjective 'nocturnal'.

Continuous urinary incontinence: continuous leakage.

Other types of incontinence (not specifically defined by the ICS)

Situational incontinence: e.g. during sexual intercourse (during penetration, during intercourse or at orgasm) or when giggling.

Postural incontinence: involuntary loss of urine associated with change of body position, e.g. rising from a seated or lying position.

Insensible or unconscious loss: leakage that patients are unaware of as it occurs and which therefore is not associated with any trigger.

years of age reported a prevalence of 4–7% (Burgio et al 1991, Miller et al 2000, Samuelson et al 2000), whilst the prevalence in women over 65 years of age was 4–14% (median 9%) (Wetle et al 1995, Nakanishi et al 1997, Brown et al 1999).

Most epidemiological studies assess all types of urinary incontinence, and few have attempted to assess the prevalence of stress incontinence. Overall, approximately half of all incontinent women have stress incontinence. Hannestad et al (2000) demonstrated that there is a regular rise in the proportion of cases of urge incontinence compared with stress incontinence from the age of 40 years. Hunskar et al (2004), in a large epidemiological study of 29,500 women in four European countries, demonstrated a similar change in the prevalence of different types of incontinence with age. The relative prevalence of mixed urinary incontinence increased with age and that of stress incontinence decreased.

Pathophysiology

Stress incontinence occurs when the intravesical pressure overcomes the closure forces of the urethra. The factors which are necessary for the urethra to remain closed include:

- pudendal innervation;
- a well-vascularized urethral mucosa and submucosa;
- urethral smooth muscle mass;
- urethral striated muscle mass; and
- intact vaginal support of the urethra from levator ani, ligaments and fascia.

Possible variations in pathophysiology of incontinence can be made considering each of these components of continence (see Chapter 49).

However, in clinical practice, it has not been possible to accurately assess the individual components of the con-

Box 52.2 Traditional risk factors for stress urinary incontinence

Parturition
Age
Oestrogen deficiency
Obesity
Pelvic support defects

tinence mechanism. Instead, a more simplistic approach has been adopted, categorizing stress incontinence into the dichotomous groups: intrinsic sphincter deficiency (ISD) and urethral hypermobility. The pathophysiology of stress incontinence is probably a continuum of the five factors listed above, and until they can be individually quantified, it will remain difficult to predict which specific treatment is most appropriate for an individual patient.

Aetiology

The possible risk factors for stress incontinence are shown in Box 52.2.

Some studies have demonstrated age as a significant risk factor for stress incontinence (Goldberg et al 2003), whilst others have only shown age to be significant in urge incontinence (Nygaard and Lemke 1996, Hannestad et al 2000, Samuelson et al 2000).

There are factors associated with age which may be responsible for incontinence rather than age alone. Resnick (1996) describes these using the mnemonic 'DIAPERS': Delirium, Infection, Atrophic changes, Pharmacological, psychological, Excess urine output, Restricted mobility and Stool impaction. Certainly, pharmacological agents such as α -blockers (e.g. doxazosin, an antihypertensive) can cause stress incontinence, and angiotensin-converting enzyme inhibitors can cause chronic cough which may aggravate stress incontinence.

Atrophic changes due to a lack of oestrogen may affect incontinence by decreasing urethral resistance and decreasing α -adrenoreceptor sensitivity in urethral smooth muscle.

There has been controversy about the role of oestrogens in the treatment of stress urinary incontinence, and a meta-analysis concluded that oestrogen did not improve the symptoms of stress incontinence (Ahmed Al-Badr Ross et al 2003).

Pregnancy, regardless of the mode of delivery, is associated with an increase in the prevalence of incontinence, although the majority of cases improve in the puerperium. Burgio et al (2003) found that 60% of women experienced urinary leakage during pregnancy, but this decreased to 11% by 6 weeks post partum. However, women who experience incontinence during pregnancy, even if it resolves in the puerperium, are more likely to experience incontinence in later life than those who have not had incontinence in pregnancy (Viktrup and Lose 2001).

In a large study involving over 15,000 women, Rortveit et al (2003) demonstrated that women who had a vaginal delivery were at greater risk of developing stress incontinence in later life compared with women who delivered by caesar-

ean section (odds ratio 2.4). The evidence regarding the impact of other obstetric factors is less clear; however, there is some evidence that use of forceps increases the risk of urinary incontinence (Farrell et al 2001, Nelson et al 2001).

There is good evidence that obesity has a causal role in the development of stress incontinence. Several studies have demonstrated an association between obesity and stress incontinence (Brown et al 1999, Hannestad et al 2000, Viktrup and Lose 2001, Goldberg et al 2003), which has been confirmed by intervention studies of bariatric surgery (Deitel et al 1988, Bump et al 1992) and weight loss programmes (Auwad et al 2008). In the treatment group, there was a reduction of stress incontinence from 61% to 12% (Deitel et al 1988).

Epidemiological studies have demonstrated that the prevalence of stress incontinence is lower in Black African women (27%) compared with White women (61%) (Bump 1993). Thom et al (2006) found similar differences when comparing Black American women with White American women, and they adjusted for age, parity, hysterectomy, oestrogen use, body mass, menopausal status and diabetes. They suggested the presence of a protective factor in Black women.

Inherent differences in connective tissue may predispose to stress incontinence. Young nulliparous premenopausal women with stress incontinence had a decreased collagen I:III ratio compared with controls (Keane et al 1997).

Assessment

The assessment involves history, examination and investigations.

A detailed history is required using language that the patient understands. The International Continence Society has produced a document which standardizes the terminology of lower urinary tract symptoms (Abrams et al 2002), although these are not terms which patients will necessarily understand. The confusion caused by the term 'stress incontinence' has been highlighted. It is preferable to use a standardized validated symptom questionnaire to elicit the patient's symptoms. Terms which are not well understood are usually removed in the validation process. Such tools can be completed by the physician or the patient. They ensure that symptoms are not missed and may help patients to describe symptoms which they find embarrassing.

It is important to ask about the impact of stress incontinence on sexual function. In one study, 68% of women stated that their sex life was affected by their urinary symptoms (Ward and Hilton 2002).

Several validated symptom questionnaires exist, and the main differences are content. Some only address symptoms of stress incontinence; for example, the Severity of Symptoms Index developed by Black et al (1996). Others, such as the Kings Health Questionnaire (Kelleher et al 1997) and the Bristol Female Lower Urinary Tract Symptom (BFLUTS) Questionnaire (Jackson et al 1996), assess all lower urinary tract symptoms, and some assess all pelvic floor symptoms (Barber et al 2001, Radley et al 2006).

Recently published national guidelines in the UK (National Institute for Health and Clinical Excellence 2006) and the USA (Agency for Health Care Policy and Research 1992, 1996) even suggested that patients who only had the symp-

toms of pure stress incontinence could be treated surgically without the need for twin channel cystometry.

Harvey and Versi (2001) evaluated the symptoms and signs of stress incontinence in predicting the presence of urodynamic stress incontinence, and found that the isolated symptom of stress incontinence had a positive predictive value of only 56% for the diagnosis of pure urodynamic stress incontinence. This implies that history alone is not reliable in establishing a diagnosis. In practice, most urogynaecologists and urologists still perform urodynamics prior to surgery. If a detailed symptom questionnaire is used to elicit the history, few patients have 'pure' stress incontinence alone.

Some symptom questionnaires, such as BLFUTS and ePAQ (Electronic Personal Assessment Questionnaire), separately assess the degree of bother that each symptom causes and the severity of the symptom (Jackson et al 1996, Radley et al 2006). Epidemiological studies have shown that although symptoms of leakage are very common, occurring in up to 60% of the population, less than half of women are bothered by them (Swithinbank et al 1999). Hence, an assessment of bother is important. The degree to which a symptom causes bother may be specific to the patient's lifestyle and personality. Each individual patient will have their own expectations about treatment and goals which they hope to achieve. In clinical practice, it is important to establish whether or not the patient's goals are attainable.

In research or audit, a formal assessment of the impact of incontinence on a patient's quality of life can be made using a quality-of-life questionnaire. There are a large number of validated quality instruments available. The International Consultation on Incontinence (ICI) has appraised and rated the existing instruments (Donovan and Bosch 2005).

When taking a history of urinary symptoms, it is also important to consider past medical and surgical history which impacts on the diagnosis. Vesicovaginal fistulae following hysterectomy are uncommon but may be missed and diagnosed as stress incontinence.

Previous continence surgery may produce new urinary symptoms including voiding dysfunction, and may decrease the success rates of future surgery.

Examination

Physical examination of all patients with stress incontinence is important. Body mass index (BMI; kg/m²) should be recorded because there is good evidence that links incontinence with high BMI (Hannestad et al 2000). General abdominal examination may reveal striae suggestive of underlying collagen disorders. There may also be evidence of benign joint hypermobility with hyperextension of joints. A general assessment of the patient's mobility and dexterity should be made with a view to considering if they would be capable of performing self-catheterization post operatively if necessary. A general neurological assessment should be performed because the presence of neurological disease may indicate an early need for urodynamics instead of conservative treatment.

Pelvic examination is performed to assess:

- urinary leakage;
- urethral mobility;

- bladder volume;
- assessment of levator ani;
- vaginal discharge;
- oestrogenization;
- perineum;
- prolapse; and
- pelvic mass.

Urinary leakage can be observed during a cough test which is normally performed in dorsal lithotomy with a comfortably full bladder. Stress incontinence is the observation of involuntary leakage from the urethra, synchronous with coughing or straining. A cough may induce a detrusor contraction which then causes leakage, but this can only be distinguished during cystometry. It is important to establish that leakage is not extraurethral from a urinary fistula or ectopic ureter.

Urethral mobility can be assessed visually. The patient is asked to cough or perform a Valsalva manoeuvre; if hypermobility is present, the anterior vaginal wall will rotate outwards and the urethral meatus towards the ceiling. Many clinicians will select the type of surgical intervention depending on the presence or absence of urethral mobility.

The levator ani can be assessed digitally just inside the posterior forchette on the left and right of the midline. The Modified Oxford Scale (Laycock and Jerwood 2001) (Table 52.1) provides a useful grading scale of the muscle, and has been shown to correlate well with surface electromyography and manometry (Haslam 1999).

It is always important to perform a visual inspection of the cervix because, occasionally, the leakage is due to copious vaginal discharge not urine. If there is doubt, an agent such as Pyridium can be used to stain urine.

The perineal skin should be assessed since it may be excoriated from inappropriate pad use, atrophy and ammoniacal dermatitis.

The presence of prolapse should be documented using a standardized assessment such as the pelvic organ quantification system (POP-Q) (Bump et al 1996). The advantage of POP-Q is that it has been shown to be reproducible.

Investigations

Pad tests

The main use of pad tests is to assess the outcome of treatment or to demonstrate urine loss. There are two types of pad test: short (≤ 2 h in duration) and long (> 24 h). Although the only standardized test is the International Continence Society's 1-h pad test, its use as an outcome measure is limited due to its poor reliability. Simons et al (2001) demonstrated that test–retest reliability of the 1-h pad test over a period of 3–10 days, even when similar bladder volumes were used, was clinically inadequate as the first and second pad test could differ by -44 to $+66$ g.

The report from the second ICI (Artibani and Cerruto 2005) concluded that 24-, 48- and 72-h pad tests had better reproducibility than the 1-h test. Compliance decreases with increasing duration of the test, and for this reason, extending the test beyond 24 h was not recommended. A pad weight gain of 1.3 g or more was considered a positive test. Attempts have been made to objectively quantify the severity

Table 52.1 The Modified Oxford Scale for pelvic floor muscles (PFM)

Muscle grade	External observation	Internal examination
0	No indrawing movement of perineal body	No activity detected
1		A mere flicker of activity
2		A weak contraction but no PFM lift
3	An indrawing movement of perineal body	A moderate PFM lift but without resistance
4		A good PFM lift against some resistance
5		An ability to lift PFM against more resistance with strong grip of examining finger

of incontinence using pad tests, but there was poor correlation between the short duration tests and subjective assessments of severity (Reid et al 2007). Correlation with the 24-h pad test was only moderate (Sandvik et al 2006). Pad tests cannot be used to diagnose the type of incontinence.

Pyridium pad test

Pyridium (phenozopyridine hydrochloride) is a compound which, when ingested, causes urine to be dyed a bright yellow/orange colour. This test can be useful to determine if the leakage experienced is urine. The test needs to be performed very carefully due to the high risk of false-positive results from perineal staining after voiding. Nygaard and Zmolek (1995) reported nearly 100% Pyridium staining in asymptomatic women during exercise; however, the mean stained area was only 2.6 mm. Some women who have excessive vaginal discharge perceive this to be urine. A Pyridium test can be useful to distinguish the two conditions.

Urodynamics

Urodynamics are discussed in detail in Chapter 51. It has not yet been proven that preoperative evaluation of women with stress urinary incontinence improves the outcome of surgery. Despite this, urodynamic studies are regularly used to assess women with stress urinary incontinence in an attempt to identify preoperative risk factors for failure or postoperative voiding dysfunction. The presence of detrusor overactivity, ISD and voiding dysfunction are theoretically associated with lower cure rates. However, the ability to measure these parameters reliably using current urodynamic techniques remains debatable, and there is little robust evidence that diagnosis of these factors should alter surgical management. There is no agreed definition of ISD. Two commonly used definitions are a maximum urethral closure pressure (MUCP) of less than 20 cmH₂O and Valsalva leak point pressures (VLPP) of less than 60 cmH₂O; however, both have limitations. MUCP is a measurement made at rest, not during the dynamic stress phase. Although VLPP is a measure of pressure in the dynamic phase during 'stress', there is variation in the pressures recorded depending on

catheter size, patient position and bladder volume. Another significant problem with VLPP is that up to 66% of women with stress incontinence experience leakage on coughing but do not leak with Valsalva (Sinha et al 2006).

There are no agreed definitions of significant postvoid residuals or voiding dysfunction in women, although many surgeons regard a preoperative flow rate less than 20 ml/s and a detrusor pressure at maximum flow of less than 20 cmH₂O as indications of higher risk of postsurgical voiding problems.

Treatment

Conservative treatment

Patients with stress incontinence may benefit from lifestyle advice. They should be encouraged to maintain a normal BMI. There is evidence that obesity is an independent risk factor for incontinence, and that weight loss in the morbidly (Deitel et al 1988, Bump et al 1992) and moderately (Subak et al 2002, Auwad et al 2008) obese will improve incontinence.

Patient are encouraged to cease smoking, reduce their caffeine intake and ensure that their fluid intake is within a normal range of 1–1.5 l/day.

There is some evidence of an association between chronic straining due to constipation and pelvic floor damage which increases the risk of incontinence (Diokno et al 1990, Spence-Jones et al 1994). However, there have been no intervention trials of the treatment of straining and urinary incontinence.

Pelvic floor muscle training

Pelvic floor muscle training (PFMT) was introduced by Kegel in the 1950s to address urinary incontinence in women (Kegel 1951). Patient education is a vital component to PFMT. The strength of pelvic floor muscle contraction should be assessed at the time of pelvic examination. On simple verbal command to squeeze their pelvic floor muscles around the examiner's fingers, many women are unable to do so, or they inadvertently contract their abdominal or gluteal muscles. Some women will even perform a Valsalva manoeuvre when asked to perform pelvic floor exercises. The pelvic examination provides an opportunity to teach the patient which muscles she needs to strengthen. Bump et al (1991) underscored the importance of education in a study in which women were given only verbal or simple written instructions to perform PFMT; 50% of the subjects were unable to perform a correct pelvic floor contraction despite their perception that they were doing so.

A large randomized controlled trial of PFMT vs no treatment in women with urodynamic stress incontinence demonstrated that self-reported cure is more likely following PFMT than no treatment (relative risk 16.8, 95% confidence interval 2.37–119.04) (Bo et al 1999).

There are very few long-term follow-up studies of PFMT. However, Lagro-Janssen and van Weel (1998) reported 5-year follow-up data on 101 of 110 women. Seven women had undergone surgery, five declined further follow-up and one had become pregnant. The results showed that the proportion of women who were dry (25%) was similar after 5

years, although the number with severe incontinence increased from 3% to 18%. Sixty-seven per cent of women remained satisfied with the outcome of treatment and did not want further treatment. Women with urge or mixed incontinence were less likely to be satisfied than women with stress urinary incontinence. Nearly half of the women (43%) who had received PFMT were no longer training at all. Logistical regression was used at 5 years to determine the relationship between age, parity, anxiety, incontinence severity, adherence to PFMT and treatment success. The only factor significantly associated with better outcome at 5 years was continued PFMT.

A Cochrane review published in 2006 investigated the effects of pelvic floor muscle training for women with urinary incontinence in comparison with no treatment, placebo or sham treatments, or other inactive control treatments (Hay-Smith and Dumoulin 2006). Six trials were included in the review, involving 403 women. The review concluded that there was some support for the widespread recommendation that PFMT be included in first-line conservative management programmes for women with not only stress urinary incontinence but also urge or mixed incontinence.

Some women are unable to isolate their pelvic floor muscles to perform PFMT, and others may perform incorrect contractions which may do more harm than good.

Biofeedback can be used to maximize rehabilitation in patients who have difficulty in performing pelvic floor contractions. Biofeedback is any signal, auditory or visual, which tells the patient that she is contracting the correct muscles. Simple verbal affirmation of a good pelvic floor muscle contraction at the time of pelvic examination is a form of biofeedback. More sophisticated forms include perineometers that consist of a rectal or vaginal probe, a visual or auditory analogue signal and abdominal electromyography electrodes. When the patient correctly contracts her pelvic floor, an analogue signal through the probe tells her she is utilizing the proper muscles. Similarly, an auditory signal via the electromyogram tells her to what degree, if any, she is recruiting her abdominal muscles. Biofeedback in addition to PFMT has been shown to be no more effective than PFMT on its own (Castleden et al 1984, Burns et al 1993); however, the group sizes were small and no trials specifically addressed the use of biofeedback in patients who could not perform a pelvic floor contraction at initial assessment.

Weighted vaginal cones represent another form of biofeedback (Figure 52.1). In theory, when a weighted cone is inserted into the vagina, the pelvic floor needs to contract to prevent it from slipping out. The patient places the lightest cone in the vagina for 15 min twice daily and goes about her normal activities. She has to contract her pelvic floor muscles to keep the cone from falling out of her vagina. When this weight becomes easy to manage, she exchanges this cone for the next heaviest. The weight of the cone is gradually increased.

A Cochrane review concluded that although limited evidence is available, it suggests that cones benefit women with stress urinary incontinence compared with no active treatment. Meta-analysis of eight trials found cones and PFMT to be no different in terms of subjective cure or improvement, pad test or pelvic muscle strength; however, PFMT was associated with a significantly greater reduction in the number of leakage episodes per day (Herbison et al 2002).

Figure 52.1 Vaginal cones.
Courtesy of Colgate Medical.

Patients who are unable to perform pelvic floor contractions despite biofeedback may be candidates for functional electrical stimulation. Direct mechanical stimulation of the pudendal nerve is delivered by either vaginal or rectal probe, causing contraction of the pelvic floor musculature. There is no robust evidence that electrical stimulation is better than PFMT alone.

Devices

The use of mechanical devices to control incontinence has been recorded since ancient Egyptian times; various elaborate but cumbersome and uncomfortable devices have been developed (Edwards 1970, Bonnar 1977). Most devices either occlude the urethra, being placed either within the urethra or over the external meatus, or are inserted into the vagina, and provide occlusive pressure against the urethra.

A Cochrane review of mechanical devices reported on six randomized controlled trials. These assessed three intravaginal and three intraurethral devices. Five of the six included studies had a very small sample size and were not large enough to detect a difference reliably. There was a lack of evidence to suggest that the use of mechanical devices is better than no treatment. There was insufficient evidence to favour one device over another, and no evidence to compare mechanical devices with other forms of treatment (Shaikh et al 2006).

Pharmacotherapy

The only pharmacological agent recommended for use in the management of stress urinary incontinence by the ICI in 2005 was duloxetine, a serotonin and noradrenaline reuptake inhibitor. Duloxetine inhibits the presynaptic reuptake of serotonin and noradrenaline in the motor neurones of the pudendal nerve, which increases the amount of these transmitters in the synapse which, in turn, increases pudendal nerve stimulation of the striated urethral sphincter. A systematic review by Mariappan et al (2007) describes the nine randomized controlled trials published comparing duloxetine with placebo. All nine trials were supported by the man-

ufacturer of duloxetine, Eli Lilly. A total of 3066 women were randomized to duloxetine ($n = 1712$) and placebo ($n = 1354$). Subjective cure and improvement of incontinence were higher in the duloxetine arms than the placebo arms, but the differences were small and only three additional patients per 100 treated were improved. The withdrawal rate was 17% in the duloxetine group and 4% in the placebo group, and approximately 75% of withdrawals were directly attributable to duloxetine. The most commonly reported side-effects were nausea, fatigue, dry mouth, insomnia, constipation, dizziness and somnolence.

Vella et al (2008) studied a group of 228 women for up to 1 year after they were commenced on duloxetine for moderate stress incontinence. After 4 weeks, only 31% were continuing with duloxetine, 45% had discontinued it due to side-effects, and 24% had discontinued it due to lack of efficacy. At 12 months, only 9% remained on treatment. Another interesting finding of this study was that 5% of women stopped taking duloxetine after 6–12 months and remained dry. This could be due to increased bulk or strength of striated muscle, or spontaneous improvement which may reflect the natural history of incontinence.

Surgical treatment

Importance of evidence-based practice: an historical perspective

Surgical procedures to treat urinary incontinence have been reported for nearly 150 years. Initially, new operations were published as single case reports. These usually included a description of the operation and the surgeon's opinion of the value of the procedure. If an outcome was assessed, it was frequently prior to discharge, invariably successful and there were no reported complications (Brown 1864, Gilliam 1896).

In 1914, Kelly and Dumm reviewed the literature on surgery for urinary incontinence; 14 studies were included in the review. There was no documented evidence of the failure of any of the procedures. Kelly and Dumm described a new operative procedure, stating that it was more successful than any proposed previously (Kelly and Dumm 1914). The study represented a significant advancement in the reporting of the outcome of surgery for incontinence. Not only did it report a greater number of cases, a series of 20, but failures were also reported. Another notable change was the reporting of both short- and long-term outcomes. Follow-up was greater than 1 year in 13 of the 20 cases. The results of this series are shown in Table 52.2 and suggest that the operation's efficacy decreased with time. Although this trend was not noted in the report, Kelly and Dumm (1914) did criticize the short follow-up period of 5 months in a series of five patients reported by Dudley in 1895, possibly indicating a recognition that failure increases with time after surgery.

In view of the high success rates that had been reported by all surgeons up until this time, it is not surprising that Kelly and Dumm's anterior repair procedure was adopted as one of the most popular operations for urinary incontinence for the next 60 years. This suggests that contemporary operations may have had significant complications or failures that were not reported in the literature.

Other factors may have influenced the widespread adoption of Kelly and Dumm's operation; it may have been related to the relative simplicity of the procedure, or due to Kelly's general credibility, high standing and influence in the field of urology and gynaecology. Possibly, his charismatic championing of the procedure promoted its adoption (Nation 1997).

In 2009, the ICI report stated that there was enough evidence from randomized controlled trials to indicate that anterior colporrhaphy should not be used in the management of stress urinary incontinence alone (Grade A) (Smith et al 2009).

Over the last 10 years, there has been a significant change in the types of operation performed for urodynamic stress incontinence. Midurethral slings have become the most frequently performed procedure. Furthermore, the overall number of continence procedures performed in the UK has increased by 25%, from approximately 8000 per annum in 1994 to 10,000 in 2005 (Hilton 2008). The reason for this is unknown but it may be due to increased awareness among women and healthcare professionals that incontinence can be treated. However, it could be that the relative technical simplicity of midurethral slings has reduced clinicians' threshold for surgical intervention.

It is important that new procedures are assessed using robust scientific evidence. The 2008 ICI report reviewed surgical intervention for stress incontinence. The categorization of levels of evidence used by the ICI was the International Consultation on Urological Disease (ICUD) modification of the Oxford System summarized in Box 52.3. A summary of the recommendations for each operation is given in Table 52.3.

Burch colposuspension

In 1949, Marshall et al reported the empirical observation that suturing the periurethral tissues to the pubic bone alleviated stress urinary incontinence (Marshall et al 1949; Figure 52.2). The Burch procedure was developed as a modification of the Marshall–Marchetti–Krantz (MMK) procedure in 1961 (Burch 1961). The purpose is to return the bladder neck to an intra-abdominal location so that it encounters the same transmural pressure as the bladder during rises in intra-abdominal pressure.

The patient is placed in the dorsal lithotomy position to permit access to the vagina. A transverse suprapubic incision

is made and the rectus abdominis is divided along its midline raphe. The surgeon's hand is then passed beneath the rectus muscles above the peritoneum in the direction of the pubic symphysis; blunt dissection in this fashion opens the retro-pubic space. The operation can be performed with the peritoneum opened or closed. Once the retropubic space is exposed, the bladder neck is identified with the operator's non-dominant hand in the vagina using a Foley balloon as a guide. A swab on a stick is then used to sweep the fatty and vascular tissue off the periurethral fascia, while the vaginal fingers elevate the anterior vagina (Figure 52.3A). Keeping the vaginal fingers elevated, the surgeon is then able to take a full-thickness bite of tissue, excluding the vaginal mucosa if possible. At least two sutures are placed on both

Box 52.3 Modified Oxford System

Levels of evidence

1. Meta-analysis of RCTs or a good-quality RCT
2. Low-quality RCT or good-quality prospective cohort
3. Good-quality retrospective case-control and case series
4. Expert opinion without evidence

Grades of recommendation (positive or negative)

- A. Usually consistent Level 1 evidence
- B. Usually consistent Level 2 or 3 or 'majority evidence' from RCTs
- C. Usually Level 4 or 'majority evidence' 2/3, Delphi processed expert opinion
- D. Evidence is inadequate or conflicting; if expert opinion, delivered without a formal analytical process

RCT, randomized controlled trial.

sides of the bladder neck, one 2 cm lateral to the urethrovesical junction and the other 2 cm lateral to the proximal urethra. Each suture is then passed through the ipsilateral iliopectineal ligament (Cooper's ligament) on the posterolateral surface of the pubic bone (Figure 52.3B). Care should be taken not to overelevate the urethrovesical junction.

In the original MMK operation, the sutures were inserted into the periosteum which caused overelevation of the urethrovesical junction. The MMK was also associated with a 2.5% incidence of osteitis pubis.

Evidence of the effectiveness of Burch colposuspension

Burch colposuspension became the gold standard against which other procedures were compared. The outcome following open colposuspension is comparable with midurethral slings [evidence level (EL) 1], bladder neck slings (EL 1/2) and transobturator slings (EL 2).

The risk of voiding dysfunction following open colposuspension is greater than following the tension-free vaginal tape (TVT) procedure (EL 1); however, it is less than following a bladder neck sling procedure (EL 1). There is a higher incidence of pelvic organ prolapse after colposuspension compared with the TVT procedure (EL 1). The 2008 ICI report stated that open colposuspension can be recommended as an effective treatment for primary stress incontinence which has longevity (Grade A).

Evidence of the effectiveness of laparoscopic colposuspension

In 1991, Vancaillie described a laparoscopic approach for Burch colposuspension (Vancaillie and Schuessler 1991).

Laparoscopic colposuspension is comparable with open colposuspension when performed by experienced laparoscopic surgeons (EL 1/2). Studies demonstrate equal or higher cure rates with the TVT procedure (EL 1/2), and the operation time for the TVT procedure is shorter and the recovery is faster (EL 1/2). The 2008 ICI report recommended that laparoscopic colposuspension was an option for the treatment of stress incontinence (Grade B), but added the caveat that it should only be performed by experienced laparoscopic surgeons (Grade D).

Tension-free vaginal tape procedure

The TVT procedure was developed by Petros and Ulmstern (1993) and Ulmstern et al (1996) (Figure 52.4). The TVT was designed to place the sling around the midurethra, where the pubourethral ligaments are assumed to insert, rather than at the bladder neck where previous slings (e.g. Aldridge slings) were placed.

Ulmstern et al (1996) described insertion under sedation, with a premedication of 5 mg ketobemidone i.m., 0.05 mg fentanyl i.m. at the start of surgery and then prior to insertion of the sling. Up to 5 mg of midazolam i.v. was used during the operation. The bladder was emptied with a Foley catheter. Close to the superior rim of the pubic bone, two 1-cm-long transverse incisions 3 cm either side of the midline are made after injection of local anaesthetic. Between 60 and 70 ml of local anaesthetic (prilocaine and adrenaline 0.25%) is injected in the abdominal skin just above the symphysis pubis and down along the back of the pubic bone to the space of Retzius. Vaginally, 40 ml of prilocaine and adrenaline 0.25% is injected into the vaginal wall sub- and paraurethrally. An incision up to 1.5 cm long is made in the midline of the suburethral vaginal wall, starting 0.5 cm from the outer urethral meatus. Laterally from this incision, a blunt dissection 0.5–1 cm long is made with the scissors either side of the urethra to allow introduction of the TVT needle. A stent is inserted into the Foley catheter to deviate the urethrovesical junction away from the path of the needle. The TVT needle perforates the urogenital diaphragm and is brought up to the abdominal incision, 'shaving' the back of the pubic bone. The procedure is then repeated on the other side, and then a cystoscopy is performed to exclude perforation; with 300 ml of saline in the bladder, the patient is asked to cough vigorously to ensure that she is dry. Importantly, the sling is only loosely placed without elevation. The plastic sheath which covers the tape is then removed, the tape is trimmed at the abdominal incisions and the incisions are closed. Ulmstern et al (1996) recommended that a size 7 Hegar dilator should be inserted into the urethra to check that the 'proximal urethra and bladder neck has an acceptable lumen and mobility'.

Evidence of the effectiveness of the tension-free vaginal tape procedure

The TVT procedure is as effective as colposuspension and traditional sling operations (EL 1/2). Operation time, hospital stay and return to normal activity are shorter with the TVT procedure than with colposuspension (EL 1/2). Postoperative voiding problems and need for prolapse surgery are more common after colposuspension (EL 1/2).

Figure 52.3 (A) Burch colposuspension. The bladder is gently mobilized to the opposite side utilizing sponge sticks. The anterior vaginal wall is elevated by the middle finger of the surgeon's non-dominant hand. The position of the sutures should be at least 2 cm lateral to the proximal urethra and bladder neck. Xs mark the ideal placement of the Burch colposuspension sutures. Inset: The anterior vaginal wall on the right side is being elevated by a vaginal finger. A Kitner is passed on top of the finger mobilizing the fat medially. (B) Sutures have been appropriately placed on each side of the proximal urethra and bladder neck. Note: figure-of-eight bites are taken through the vagina. Double-armed sutures are utilized so the end of each suture can be brought up through the ipsilateral Cooper's ligament, thus allowing the sutures to be tied above the ligament. Inset: Detail of the suture being placed over the surgeon's vaginal finger. Note: suture should include full-thickness vaginal wall excluding the epithelium. Source: Karram MM, Baggish MS (eds) 2001 *Atlas of Pelvic Anatomy and Gynecologic Surgery*. Harcourt, New York.

The TVT procedure is more effective than the SupraPubic ARC (SPARC) procedure (EL 2), and the intravaginal sling-plasty procedure is comparable to the TVT procedure in terms of efficacy but has a higher complication rate (EL 2) (Smith et al 2008).

Transobturator tape procedure

In 2001, Delorme described a new procedure using transobturator tape based on the principles of the TVT procedure, but designed to avoid the risk of bladder perforation (Ward and Hilton 2002) and the rare complication of bowel perforation (Leboeuf et al 2003). Instead of passing the tape through the retropubic space, it is inserted via the obturator foramen. Delorme described an outside-in technique in which the tape is introduced through the skin of the groin, obturator foramen and out of the vaginal incision (Delorme 2001) (Figure 52.5).

Evidence of the effectiveness of the transobturator tape procedure

To date, two meta-analyses of transobturator tape procedures have been published and both concluded that there was limited evidence (Latthe et al 2007, Sung et al 2007). No objective outcomes were reported in the meta-analysis because these were only reported in one randomized controlled trial. The analysis by Latthe et al (2007) considered the two different routes of transobturator tapes and excluded SPARC retropubic tapes. When compared with the TVT procedure, the subjective cure of stress urinary incontinence was slightly worse in the TVT obturator procedure, inside-to-out group (odds ratio 0.69, 95% confidence interval 0.42–1.14), although this was not statistically significant. The transobturator tape procedures were associated with fewer bladder injuries and voiding difficulty than the TVT procedure, but more groin pain and vaginal mesh erosion (Latthe et al 2007).

The 2008 ICI report concluded that retropubic and transobturator tape procedures perform equally at a short-term follow-up of 6–12 months, and overall reported complication rates are comparable (EL 1/2).

Figure 52.4 Tension-free vaginal tape. The needles are passed to either side of the midurethra with the help of the removable handle. Also shown is the catheter guide that is used during passing of the tape to divert the bladder neck away from the path of the needle.

Figure 52.5 The outside-in technique in which the transobturator tape (TVTO) is introduced through the skin of the groin, obturator foramen and out of the vaginal incision.

Minitape procedures

A number of manufacturers have developed minitapes or single incision slings (SISs). They only require a vaginal incision. Potentially these SISs could be inserted under local anaesthetic as an office procedure; however, there is currently inadequate data to use these tapes outside of a research setting. Figure 52.6 shows the TVT Secur, the first of these minitapes.

Bladder neck sling procedures

Slings are performed with the patient in the dorsolithotomy position. A horizontal incision is made approximately 2 cm above the pubic symphysis. The subcutaneous fat is dissected, providing visualization of the rectus fascia. If rectus fascia is to be harvested from the patient, the incision may need to be longer. An alternative source of sling material is fascia lata that is obtained from the patient's thigh by excision or the use of a fascial stripper (Figure 52.7A). Once a 4 × 4 cm piece (for a patch-type sling) or two 2 × 8 cm portions (which are sewn end to end to create a long enough graft for a full-length sling) of fascia have been excised, the defect is closed with delayed absorbable suture. If the patient permits, cadaveric donor fascia can be used. It saves time, is

Figure 52.6 The TVT Secur.

Courtesy of Gynecare/Ethicon.

abundant and risk is minimal. The fascia is kept in saline until it is required.

Attention is then turned to the vagina where a midline anterior vaginal incision is made. The vaginal wall is dissected off the underlying bladder and urethra. This dissection is continued laterally to both sides of the bladder neck until the underside of the pubic symphysis is encountered. At this point, a curved instrument such as a Kelly clamp or Stamey needle is passed from the abdominal incision, through the rectus fascia just above the symphysis. It traverses through the retropubic space by keeping the instrument in constant contact with the back of the pubic bone, finally emerging into the vagina where the vaginal dissection is carried to the underside of the pubic bone. The entry of the instrument into the vaginal dissection is assisted by placing a vaginal finger lateral to the bladder neck along the underside of the symphysis. The instrument is aimed at this finger and guided into the vagina. The same procedure is repeated on the other side.

When placing a full-length sling, the central portion of the graft is sewn in place at the level of the bladder neck with an absorbable suture. Each end of the sling is then pulled up through the retropubic space using the previously passed instruments (Figure 52.7B). Once the end of the graft is above the level of the abdominal rectus fascia, it is either sewn to the fascia on either side or in the midline to the other end of the graft. For patch slings, the tissue is folded or trimmed to the correct size then sewn in place at the bladder neck (Figure 52.7C). A permanent suture is then fixed to either side of the patch and the ends are pulled up through the retropubic space to the abdominal incision, as described for the full-length sling. Similarly, the ends of the permanent suture can be tied to one another across the midline. Alternatively, the Stamey needle can be passed through the rectus fascia in two different locations on both

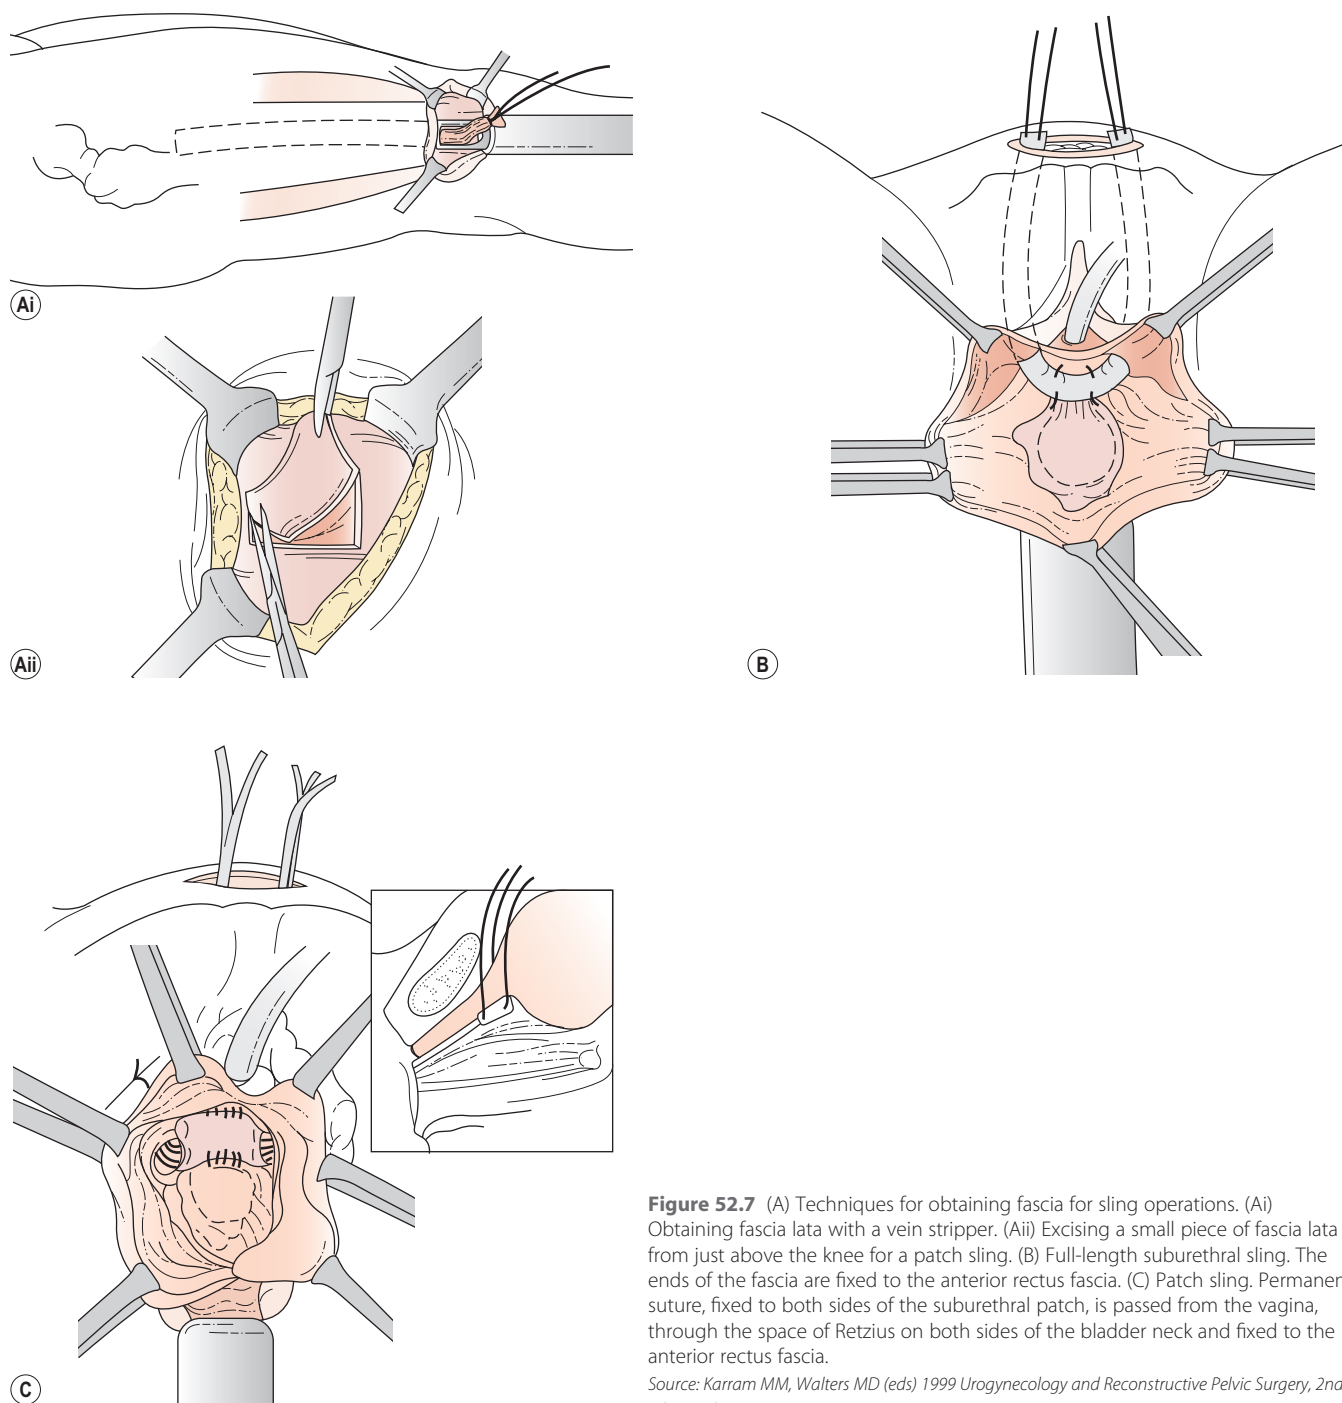

Figure 52.7 (A) Techniques for obtaining fascia for sling operations. (Ai) Obtaining fascia lata with a vein stripper. (Aii) Excising a small piece of fascia lata from just above the knee for a patch sling. (B) Full-length suburethral sling. The ends of the fascia are fixed to the anterior rectus fascia. (C) Patch sling. Permanent suture, fixed to both sides of the suburethral patch, is passed through the vagina, through the space of Retzius on both sides of the bladder neck and fixed to the anterior rectus fascia.

Source: Karram MM, Walters MD (eds) 1999 *Urogynecology and Reconstructive Pelvic Surgery*, 2nd edn. Mosby, St Louis.

sides (a total of four passes), and each end of the permanent suture can be brought up through its own tract. The two left ends are tied to one another on the left side and the two right ends are tied on the right.

The most challenging part of a sling procedure is determining the correct amount of tension to apply. The balance one tries to obtain is continence without creating postoperative voiding dysfunction. In general, the sling should be tied under as little tension as possible. This can be accomplished by placing a right-angle clamp between the sling and the bladder neck at the time when the abdominal portion of the

graft is being tied. Some advocate using a Q-tip to assist in tightening the sling until an angle of 0° to $+10^{\circ}$ is achieved. Others perform this portion of the procedure with a cystoscope in place, and some simply fill the bladder and adjust the sling until there is no leakage.

Evidence of the effectiveness of bladder neck sling procedures

The 2009 ICI report stated that rectus sheath fascial slings are effective (EL 1). There was no high-level evidence comparing autologous, biological and synthetic slings, although

Figure 52.8 Technique for transurethral injection of urethral bulking agents. (A) Bladder neck open prior to injection. (B) Submucosal placement of needle at one site partially closes bladder neck. (C) Complete closure of bladder neck at completion of the procedure.

Source: Karram MM, Walters MD (eds) 1999 *Urogynecology and Reconstructive Pelvic Surgery*, 2nd edn. Mosby, St Louis.

autologous slings may be more effective (EL 2) and adverse events may be more common with alternative materials (EL 3). The ICI recommended that the autologous fascial sling procedure is an effective treatment for stress urinary incontinence which has longevity (Grade A). However, further research is required to compare autologous sling procedures with other sling materials.

Urethral bulking agents

For over 70 years, urethral bulking agents have been used for the treatment of stress urinary incontinence. They are injected transurethraly (Figure 52.8) or periurethraly (Figure 52.9) under direct cystoscopic guidance or through a guidance device.

The ideal urethral bulking agent has not yet been identified, nor has the injection route, location for injection or the optimal number of injection sites.

Figure 52.9 Technique for periurethral injection of urethral bulking agents. Source: Karram MM, Walters MD (eds) 1999 *Urogynecology and Reconstructive Pelvic Surgery*, 2nd edn. Mosby, St Louis.

The mechanism of action is not fully understood, but it may be an obstructive effect. The long-term success may not correlate with the endoscopic appearance at the conclusion of the injection.

A variety of substances have been reported to be safe and effective. These include bovine glutaraldehyde cross-linked bovine collagen (Contigen®), polytetrafluoroethylene (Teflon®), polydimethyl-siloxane elastomer (Macroplastique®), porcine dermal implant (Permacol®), carbon-coated zirconium beads (Durasphere®), non-animal stabilized hyaluronic acid/dextranomer NASHA/Dx (Zuidex®), calcium hydroxyapatite (Coaptite®), ethylene vinyl alcohol (Uryx®, Tegress®) and, most recently, polyacrylamide hydrogel (Bulkamid®).

Evidence of the effectiveness of periurethral injection therapy

A Cochrane review in 2007 stated that the evidence was inadequate to inform practice; however, injection therapy may represent a useful option for short-term symptomatic relief amongst selected women with comorbidity that precludes anaesthesia (Keegan et al 2007).

With regard to urethral bulking agents, the 2008 ICI report concluded that the evidence of benefit from urethral bulking agents is limited, and appears to be short term.

There is no evidence that any one bulking agent has an advantage over any other (EL 2). Conventional surgery appears to provide a greater cure rate; however, the risk of complications may be greater (EL 2). There are no studies comparing urethral bulking agents with non-surgical treatments. The ICI recommended that when urethral bulking agents are to be used, women should be made aware that repeat injections are likely to be required to achieve efficacy, that efficacy diminishes with time, and efficacy is inferior to that of conventional surgical techniques; they should also be made aware of alternative minimally invasive procedures (Grade B).

KEY POINTS

1. Stress urinary incontinence (SUI) is the complaint of involuntary leakage on effort or exertion, or on sneezing or coughing.
2. The term stress incontinence can be misinterpreted by patients. Some make the assumption that 'stress' refers to their psychological state.
3. Prevalence depends on the population studied, the definition of incontinence used and the degree of bother assessed.
4. Between 4% and 7% of women under 60 years old experience daily incontinence.

5. There are multiple risk factors for the development of SUI, including parturition, advanced age, oestrogen deficiency, obesity and loss of pelvic tissue support.
6. Taking a good history is paramount because there has been a move to initiate conservative treatments prior to urodynamic assessment.
7. The ICI, NICE and Cochrane reviews provide up-to-date evidence about the efficacy of treatments.
8. All patients should be given a trial of conservative measures. These interventions may improve symptoms in up to 75% of patients.
9. The risks and untoward effects of the surgical options must be discussed in detail with the patient.
10. Patients with persistent recurrent SUI must be evaluated thoroughly to rule out complications of their prior incontinence operation.

Introduction

The normal adult human bladder is under voluntary control and does not contract, except during micturition. Conversely, an overactive bladder is one which contracts involuntarily or can be provoked to do so. Raised bladder pressure was first reported in certain neurological conditions over 70 years ago (Rose 1931, Langworthy et al 1936), but its clinical significance was not appreciated until 1963 when Hodgkinson et al demonstrated urinary incontinence as a result of detrusor contractions in 64 neurologically normal women. They called this condition 'dyssynergic detrusor dysfunction'. Various other names have been used, including 'detrusor instability', 'detrusor reflex instability', 'overactive bladder' and 'detrusor hyperreflexia'. The terminology of lower urinary tract dysfunction has been revised and standardized by the International Continence Society in order to clarify understanding of patient symptoms and diagnosis (Abrams et al 2002).

Overactive Bladder

The term 'overactive bladder' (then 'unstable bladder') was first used by Bates et al (1970) to describe 'the objectively measured loss of ability to inhibit detrusor contraction even when it is provoked to contract by filling, change of posture, coughing, etc.' More recently, overactive bladder has been

redefined as the symptom-based diagnosis of 'urgency, with or without urge incontinence usually with frequency and nocturia' (Abrams et al 2002).

Detrusor Overactivity

The symptoms of overactive bladder are due to involuntary contractions of the detrusor muscle during the filling phase of the micturition cycle. These involuntary contractions are termed 'detrusor overactivity' (Abrams et al 2002) and are mediated by acetylcholine-induced stimulation of bladder muscarinic receptors (Andersson 1997). However, overactive bladder is not synonymous with detrusor overactivity, as the former is a symptom-based diagnosis whilst the latter is a urodynamic diagnosis. It has been estimated that 64% of patients with overactive bladder have urodynamically proven detrusor overactivity, and 83% of patients with detrusor overactivity have symptoms suggestive of overactive bladder (Hashim and Abrams 2006).

Incidence

Epidemiological studies have reported the overall prevalence of overactive bladder in women to be 16.9%, suggesting that there could be 17.5 million women in the USA who suffer from the condition. The prevalence increases with age,

being 4.8% in women under 25 years of age and 30.9% in those over 65 years of age (Stewart et al 2001). This is supported by recent prevalence data from Europe in which 16,776 interviews were conducted in a population-based survey (Milsom et al 2001). The overall prevalence of overactive bladder in individuals aged 40 years and above was 16.6%, and this increased with age. Frequency was the most commonly reported symptom (85%), whilst 54% complained of urgency and 36% complained of urge incontinence. When considering management, 60% had consulted a physician, although only 27% were currently receiving treatment.

More recently, a further population-based survey of lower urinary tract symptoms in Canada, Germany, Italy, Sweden and the UK has reported on 19,165 men and women over the age of 18 years (Irwin et al 2006). Overall, 11.8% were found to complain of symptoms suggestive of overactive bladder and 64.3% reported at least one urinary symptom. Nocturia was the most prevalent lower urinary tract symptom, being reported by 48.6% of men and 54.5% of women.

Aetiology

No specific underlying cause for overactive bladder has been identified, but possible aetiologies include idiopathic, psychosomatic and neurogenic causes in addition to incontinence surgery and outflow obstruction (men).

During infancy, prior to toilet training, it is normal for the bladder to contract uninhibitedly at a critical volume, and overactive bladder may be the result of poorly learnt bladder control. Zoubek et al (1990) studied 46 toilet-trained children, all of whom developed isolated urinary frequency. In 40% of cases, a 'trigger' was identified prior to the onset of symptoms. This often involved problems at school. All cases were self-limiting or resolved following counselling or removal of the 'trigger'. In addition, there is a strong association between childhood nocturnal enuresis and overactive bladder presenting in adult life (Whiteside and Arnold 1975).

The psychoneurotic status of women with overactive bladder has been assessed by several authors, with conflicting results. Walters et al (1990) evaluated 63 women with incontinence and 27 continent controls using formal psychometric testing. They reported no difference in the test results between women with urodynamic stress incontinence and those with overactive bladder. Women with overactive bladder scored significantly higher than controls on the hypochondriasis, depression and hysteria scales. They concluded that these abnormalities may be related to incontinence in general and not to the specific diagnosis. Norton et al (1990) psychiatrically assessed 117 women prior to urodynamic investigation. There was no increased psychiatric morbidity in women with detrusor overactivity compared with women with urodynamic stress incontinence. Interestingly, women in whom no urodynamic abnormality could be detected had the highest scores for anxiety and neuroticism. These levels were comparable with those of psychiatric outpatients.

Neurological lesions such as multiple sclerosis and spinal cord injuries may cause uninhibited bladder contractions,

which play an aetiological role in a small group of women with neurogenic detrusor overactivity.

In addition, following incontinence surgery, there is an increased incidence of detrusor overactivity (Cardozo et al 1979, Steel et al 1985, Brown and Hilton 1999) for which no specific cause has been found, but it may be due to extensive dissection around the bladder neck as it is more commonly seen after multiple previous operations. Alternatively, it may be failure to diagnose the abnormality prior to surgery or relative outflow obstruction caused by the operation itself. Outflow obstruction is rare in women and does not seem to cause detrusor overactivity in the same way that prostatic hypertrophy does in men. The increased incidence of detrusor overactivity in the elderly may be due to the onset of occult neuropathy (e.g. senile atherosclerosis or dementia).

Muscarinic Receptors

Molecular cloning studies have revealed five distinct genes for muscarinic acetylcholine receptors in rats and humans, and it has been shown that five receptor subtypes (M_1 – M_5) correspond to these gene products (Caulfield and Birdsall 1998). In the human bladder, the occurrence of mRNA encoding M_2 and M_3 subtypes has been demonstrated, although not for M_1 (Yamaguchi et al 1996). The M_3 receptor is thought to cause a direct smooth muscle contraction (Harris et al 1995). Whilst the role of the M_2 receptor has not yet been clarified, it may oppose sympathetically mediated smooth muscle relaxation (Hegde et al 1997) or result in the activation of a non-specific cationic channel and inactivation of potassium channels (Hegde and Eglen 1999). In general, it is thought that the M_3 receptor is responsible for the normal micturition contraction, although in certain disease states, such as neurogenic bladder dysfunction, the M_2 receptors may become more important in mediating detrusor contractions (Braverman and Ruggieri 1998).

Pathophysiology

A detrusor contraction is initiated in the rostral pons. Efferent pathways emerge from the sacral spinal cord as the pelvic parasympathetic nerves (S2, 3 and 4) and run forwards to the bladder. Whilst preganglionic neurotransmission is predominantly mediated by acetylcholine acting on nicotinic receptors, transmission may also be modulated by adrenergic, muscarinic, purinergic and peptidergic presynaptic receptors.

Acetylcholine is released by the postganglionic nerves at the neuromuscular junction, and results in a coordinated detrusor contraction mediated through muscarinic receptors. However, adenosine triphosphate (ATP) also has a role (Burnstock 2001) mediated through non-adrenergic, non-cholinergic receptors (O'Reilly et al 2002).

Conversely, sympathetic innervation is from the hypogastric and pelvic nerves acting on β -adrenoreceptors causing relaxation of the detrusor muscle. Thus, a balance between sympathetic and parasympathetic stimulation is required for normal detrusor function.

The pathophysiology of detrusor overactivity remains unclear. In-vitro studies have shown that in cases of idio-

pathic detrusor overactivity, the detrusor muscle contracts more than normal. These detrusor contractions are not nerve mediated and can be inhibited by the neuropeptide vasoactive intestinal polypeptide (Kinder and Mundy 1987). Other studies have shown that increased α -adrenergic activity causes increased detrusor contractility (Eaton and Bates 1982). There is evidence to suggest that the pathophysiology of idiopathic and obstructive overactive bladder is different. From animal and human studies on obstructive overactivity, it seems that the detrusor develops postjunctional supersensitivity, possibly due to partial denervation (Sibley 1997), with reduced sensitivity to electrical stimulation of its nerve supply but greater sensitivity to stimulation with acetylcholine (Sibley 1985). If outflow obstruction is relieved, the detrusor can return to normal behaviour and reinnervation may occur (Speakman et al 1987).

Relaxation of the urethra is known to precede contraction of the detrusor in a proportion of women with detrusor overactivity (Wise et al 1993a). This may represent primary pathology in the urethra which triggers a detrusor contraction, or may merely be part of a complex sequence of events which originate elsewhere. It has been postulated that incompetence of the bladder neck, allowing passage of urine into the proximal urethra, may result in an uninhibited contraction of the detrusor. However, Sutherst and Brown (1978) were unable to provoke a detrusor contraction in 50 women by rapidly infusing saline into the posterior urethra using modified urodynamic equipment.

Brading and Turner (1994) suggest that the common feature in all cases of detrusor overactivity is partial denervation of the detrusor, which may be responsible for altering the properties of the smooth muscle, leading to increased excitability and increased ability of activity to spread between cells, resulting in coordinated myogenic contractions of the whole detrusor (Brading 1997). They dispute the concept of neurogenic detrusor overactivity (i.e. increased motor activity to the detrusor) as the underlying mechanism in detrusor overactivity, proposing that there is a fundamental abnormality at the level of the bladder wall, with evidence of altered spontaneous contractile activity consistent with increased electrical coupling of cells, a patchy denervation of the detrusor and a supersensitivity to potassium (Mills et al 2000). Charlton et al (1999) suggest that the primary defect in the idiopathic and neuropathic bladders is a loss of nerves accompanied by hypertrophy of the cells, and an increased production of elastin and collagen within the muscle fascicles.

Clinical Presentation

Symptoms and signs

Overactive bladder usually presents with a multiplicity of symptoms. Those most commonly seen are urgency, daytime frequency, nocturia, urge incontinence, stress incontinence, nocturnal enuresis and often coital incontinence. However, it is important to remember that there are numerous other causes of urgency and frequency (Box 53.1).

Iatrogenic frequency and polyuria due to numerous cups of tea or coffee and fizzy drinks should be detected by means of a frequency/volume chart. Most women who are inconti-

Box 53.1 Common causes of frequency and urgency of micturition

Urological

- Urinary tract infection
- Detrusor overactivity
- Small-capacity bladder
- Interstitial cystitis
- Chronic urinary retention/chronic urinary residual
- Bladder mucosal lesion (e.g. papilloma)
- Bladder calculus
- Urethral syndrome
- Urethral diverticulum
- Urethral obstruction

Gynaecological

- Pregnancy
- Genuine stress incontinence
- Cystocele
- Pelvic mass (e.g. fibroids)
- Previous pelvic surgery
- Radiation cystitis/fibrosis
- Postmenopausal urogenital atrophy
- Sexual
- Coitus
- Sexually transmitted disease
- Contraceptive diaphragm

Medical

- Diuretic therapy
- Upper motor neurone lesion
- Impaired renal function
- Congestive cardiac failure (nocturia)
- Hypokalaemia
- Endocrine
- Diabetes mellitus
- Diabetes insipidus
- Hypothyroidism
- Psychological
- Excessive drinking
- Habit
- Anxiety

nent develop voluntary frequency, initially in order to try to reduce leakage. Nocturia is also a common symptom in overactive bladder, occurring in almost 70% of cases (Cardozo and Stanton 1980). However, being woken from sleep for some other reason and voiding because one is awake does not constitute nocturia. There is an increasing incidence of nocturia with increasing age, and it is normal for women over 70 years of age to void twice during the night, and women over 80 years of age to void three times during the night.

Urge incontinence is usually preceded by urgency (a sudden compelling desire to pass urine which is difficult to defer) and is due to an involuntary detrusor contraction. However, some women are unaware of any sensation associated with their detrusor contractions, and just notice that they are wet. There seems to be a strong correlation between

nocturnal enuresis, either childhood or current, and idiopathic detrusor overactivity (Whiteside and Arnold 1975). Some women complain of incontinence during sexual intercourse, and they can be broadly divided into two groups: those who leak during penetration and tend to have urodynamic stress incontinence, and those who leak at orgasm who tend to have detrusor overactivity (Hilton 1988).

The most noticeable feature of the symptomatology of overactive bladder is its infinite variability. Some patients may be severely incapacitated when at work but virtually asymptomatic when they go on holiday. Others complain of severe urgency and frequency in the mornings but void normally during the rest of the day, and others say that they are incontinent when they do the washing up or put the door key in the lock ('latch-key incontinence').

There are no specific clinical signs in women with overactive bladder, but it is always important to look for vulval excoriation, urogenital atrophy, a urinary residual and stress incontinence. Occasionally, an underlying neurological lesion such as multiple sclerosis will be discovered by examining the cranial nerves and S2, 3 and 4 outflow.

Quality of Life

Quality of life (QoL) has been defined as including 'those attributes valued by patients including their resultant comfort or sense of well being; the extent to which they were able to maintain reasonable physical, emotional, and intellectual function; the degree to which they retain their ability to participate in valued activities within the family and the community' (Naughton and Shumaker 1996). This helps to emphasize the multidimensional nature of QoL, and the importance of considering the patient's perception of their own situation with regard to non-health-related aspects of their life (Gill and Feinstein 1974).

QoL is assessed by the use of questionnaires completed by the patient alone or as part of the consultation, and its measurement allows the quantification of morbidity and the evaluation of treatment efficacy. It also acts as a measure of how lives are affected and coping strategies adopted. It is estimated that 20% of adult women suffer some degree of life disruption secondary to lower urinary tract dysfunction (Burgio et al 1991).

Generic questionnaires, such as the Short Form 36 (Jenkinson et al 1993), are general measures of QoL and are therefore applicable to a wide range of populations and clinical conditions, whilst disease-specific questionnaires have also been designed to focus on lower urinary tract symptoms. Generic questionnaires are not specific to a particular disease, treatment or age group and hence allow broad comparisons to be made. Consequently, they lack sensitivity when applied to women with lower urinary tract symptoms, and may be unable to detect clinically important improvement.

The King's Health Questionnaire is a reliable, validated, disease-specific tool used to assess women with lower urinary tract dysfunction (Kelleher et al 1997a). Experience using this questionnaire has shown that incontinence impact scores were significantly worse for women with detrusor overactivity than for those with urodynamic stress incontinence, and significantly better in women with normal urodynamics.

Investigations

Urine culture

A midstream specimen of urine should be sent for microscopy, culture and sensitivity in all cases of incontinence. An infection may contribute to the symptomatology, and investigations, which are mainly invasive, may exacerbate this. Such investigations are certainly uncomfortable when an infection is present and the results may be inaccurate.

Frequency/volume chart

It is the authors' practice to send all patients a frequency/volume chart with their appointment for urodynamic investigations, so that their fluid intake and voiding pattern can be evaluated. As well as the number of voids and incontinence episodes, the mean volume voided over a 24-h period can also be calculated as well as the diurnal and nocturnal volumes. They are asked to complete the chart (Figure 53.1) for 5 days, but are told that they need not measure their

voided volumes when at work if this proves difficult. In addition, there is now evidence that 3- and 4-day frequency/volume charts are as accurate as 7-day diaries (Brown et al 2003). Some women find that this is a useful exercise, similar to home bladder drill.

Uroflowmetry

Although voiding difficulties are uncommon in women, a large chronic urinary residual may present with symptoms of urgency and frequency of micturition, so it is relevant to measure the urine flow rate prior to urodynamic assessment. In uncomplicated idiopathic detrusor overactivity, the flow rate is usually high and the voiding time short, with only a small volume being passed each time.

Cystometry

The urodynamic diagnosis of detrusor overactivity is made when detrusor contractions are seen on a cystometrogram. Detrusor overactivity is defined as 'a urodynamic observation characterised by involuntary detrusor contractions during filling which may be spontaneous or provoked' (Abrams et al 2002). The recorded detrusor pressure rise may

take different forms on the cystometrogram trace. Most commonly, uninhibited systolic contractions occur during bladder filling (Figures 53.2 and 53.3). Not all cases of detrusor overactivity will be diagnosed on supine filling alone (Turner-Warwick 1975). Some show an abnormal detrusor pressure rise on a change of posture and may void precipitately on standing (Figure 53.4), or there may be detrusor contractions provoked by coughing which manifest as stress incontinence. Sometimes, a steep detrusor pressure rise occurs during bladder filling. This usually represents low compliance of the detrusor, but may be due to involuntary detrusor activity in some cases. It can be difficult to differentiate between systolic (phasic) detrusor overactivity and low compliance, which may coexist. Both conditions usually produce similar symptoms.

During the cystometrogram, it is important to ask the patient about her symptoms and relate them to the recorded changes. Most patients will complain of urgency when a detrusor contraction occurs, or urge incontinence if the detrusor pressure exceeds the urethral pressure. Thus, in order to diagnose or exclude detrusor overactivity, subtracted provocative cystometry must be employed. Other common, although not universal, features of the cystometrogram in women with detrusor overactivity are early first sensation,

Figure 53.3 Cystometrogram showing neurogenic detrusor overactivity during filling in a patient with multiple sclerosis.

small bladder capacity and inability/or difficulty in interrupting the urinary stream. The latter may be associated with a high isometric detrusor contraction (Figure 53.4) or, if videocystourethrography is performed, slow or absent 'milk-back' of contrast medium from the proximal urethra into the bladder.

Ambulatory urodynamics

There are three main components to an ambulatory urodynamic system: the transducers, the recording unit and the analysing system. The transducers are solid state and are mounted on 5 French and 7 French bladder and rectal catheters. It is the authors' practice to use two bladder transducers in order to reduce artifact. The recording system should be portable in order to allow freedom of movement, with a digital memory aiding compression and expansion of the traces which are obtained. An event marker is attached to the recording unit allowing the patient to mark episodes of urgency and also to document voids. In addition, the recording unit is attached to an electronic (Urilos) pad to document episodes of leakage during the study, and should have the facility to attach to a flow meter in order to record pressure flow voiding studies. The ambulatory protocol at Kings College Hospital consists of a 4-h period during which time

the patient is asked to drink 200 ml of fluid every 30 min and also to keep a diary of events and symptoms. On completion of the test, the trace is analysed with the patient using a personal computer and the urinary diary. Detrusor overactivity should only be diagnosed if there is a detrusor contraction noted on both bladder lines in the presence of symptoms (Figure 53.5).

The clinical usefulness of ambulatory urodynamics is limited by the high prevalence of abnormal detrusor (38–69%) contractions in asymptomatic volunteers (van Waalwijk van Doorn et al 1992, Robertson et al 1994, Heslington and Hilton 1996). However, the diagnosis of detrusor overactivity is highly dependent on interpretation of the results; in a prospective study of 26 asymptomatic women, the incidence of detrusor overactivity varied from 11.5% to 76.9% depending on the criteria used (Salvatore et al 1998, 2001). If the criteria for defining abnormal detrusor contractions are a simultaneous pressure rise on both bladder lines in addition to patient-reported symptoms of urgency or urge incontinence, the findings are normal in 90% of women; this is similar to that reported in laboratory urodynamics. In order to improve the diagnostic discrimination of ambulatory urodynamic studies, a standardization document has been published (van Waalwijk van Doorn et al 2000).

Figure 53.4 Cystometrogram showing low compliance with a high isometric contraction (Piso) during bladder filling.

Cystourethroscopy

Endoscopy is not helpful in diagnosing detrusor overactivity but may be used to exclude other causes for the symptoms, such as a bladder tumour or calculus. Coarse trabeculation and diverticulae of the bladder may be noted in longstanding cases of detrusor overactivity.

Videocystourethrography

Additional information may be acquired by undertaking videocystourethrography with pressure and flow studies, rather than subtracted cystometry, and this may also increase the diagnostic accuracy. Bladder diverticulae (Figure 53.6) and trabeculation (Figure 53.7) may be observed during videocystourethrography, and vesicoureteric reflux may be observed when severe detrusor overactivity has caused upper urinary tract damage.

Treatment

Not all women with overactive bladder require treatment. Once the problem has been explained to them, some will

be able to control their own symptoms by behavioural modification, such as drinking less and avoiding tea, coffee and alcohol (which are bladder stimulants).

However, most women with overactive bladder request treatment, and although many different therapies have been tried, none have proved universally satisfactory. The major therapeutic interventions which are currently in use attempt to either improve central control, as in behavioural intervention, or alter detrusor contractility using drugs or surgical denervation techniques. When these measures fail to control the patient's symptoms adequately over a long period of time, more invasive treatment may be employed. Conventional bladder neck surgery (as is used to treat urodynamic stress incontinence) rarely cures women with detrusor overactivity and may make the symptoms of urgency and frequency worse.

Methods of treatment currently employed are behavioural intervention, drug therapy, intravesical botulinum toxin and neuromodulation. For patients with intractable overactive bladder who are resistant to therapy, surgical procedures such as augmentation cystoplasty and urinary diversion may have a role.

Historically, other types of treatment which have been tried include vaginal denervation (Hodgkinson and Drukker

Figure 53.5 Cystometrographic recording obtained during ambulatory monitoring. A detrusor contraction (Pdet) is associated with pressure rises in both bladder lines (Pves, Pura) and leakage of urine (loss).

1977, Warrell 1977, Ingleman-Sundberg 1978), caecocystoplasty, selective sacral neurectomy (Torrens and Griffiths 1974), cystodistension (Ramsden et al 1976, Higson et al 1978, Pengelly et al 1978) and bladder transection (Mundy 1983). All give some short-term benefit in carefully selected cases, but may produce significant morbidity. None have stood the test of time.

General management

All incontinent women benefit from advice regarding simple measures which they can take to help alleviate their symptoms. Many patients drink too much and they should be told to reduce their fluid intake to between 1 and 1.5 l/day (Swithinbank et al 2005), and to avoid tea, coffee and alcohol if these exacerbate their problem. In addition, there is also increasing evidence to suggest that weight loss may improve symptoms of urinary incontinence (Subak et al 2009). The use of drugs which affect bladder function, such as diuretics and α -adrenoreceptor antagonists, should be reviewed and stopped if possible. If there is coexistent urodynamic stress incontinence, pelvic floor exercises may also be helpful.

It is usually preferable, in cases of mixed incontinence, to treat the overactive bladder prior to resorting to surgery for urethral sphincter incompetence. Such treatment may

obviate the need for surgery (Karram and Bhatia 1989). In addition, there is always the risk that the incontinence operation may exacerbate the symptoms of overactive bladder.

For a peri- or postmenopausal woman, local oestrogen replacement therapy is unlikely to cure the problem, but may improve urogenital atrophy and increase the sensory threshold of the bladder, and may also make urinary symptoms easier to cope with. The most degrading aspect of urinary incontinence for many patients is the odour and staining of their clothes, and this can be helped by good advice regarding incontinence pads and garments.

Pharmacology

Drug therapy has an important role in the management of women with urinary symptoms caused by overactive bladder, although there are no drugs which act specifically on the bladder and urethra and do not have systemic effects. The large number of drugs available is indicative of the fact that none are ideal, and it is often their systemic adverse effects which limit their use in terms of efficacy and compliance (Kelleher et al 1997b). The pharmacology of drugs and recommendations for usage have been reviewed recently by the 4th International Consultation on Incontinence (Andersson et al 2009) (Table 53.1).

Figure 53.6 Multiple bladder diverticulae.

Figure 53.7 Trabeculated bladder secondary to longstanding overactive bladder, with bladder diverticulae and bilateral vesicoureteric reflux. The bladder neck is open during a detrusor contraction with associated leakage.

Antimuscarinic drugs

The detrusor is innervated by the parasympathetic nervous system (pelvic nerve), the sympathetic nervous system (hypogastric nerve) and by non-cholinergic, non-adrenergic neurones. The motor supply arises from S2, 3 and 4 and is conveyed by the pelvic nerve. The neurotransmitter at the neuromuscular junction is acetylcholine, which acts upon muscarinic receptors. Antimuscarinic drugs should therefore be of use in the treatment of detrusor overactivity. Atropine is the classic non-selective anticholinergic drug with antimuscarinic activity; however, its non-specific mode of action makes it unacceptable for clinical use because of the high incidence of side-effects. All antimuscarinic agents produce competitive blockade of acetylcholine receptors at postganglionic parasympathetic receptor sites. They all, to a lesser or greater extent, have the typical side-effects of dry mouth, blurred vision, tachycardia, drowsiness and constipation. Unfortunately, virtually all the drugs which are truly beneficial in the management of overactive bladder produce these unwanted systemic side-effects.

Tolterodine

Tolterodine is a competitive muscarinic receptor antagonist with relative functional selectivity for bladder muscarinic

Table 53.1 Drugs used in the treatment of overactive bladder

**See Appendix.

receptors (Ruscin and Morgenstern 1999). Whilst it shows no specificity for receptor subtypes, it does target the muscarinic receptors in the bladder rather than those in the salivary glands (Nilvebrant et al 1997). Several randomized, double-blind, placebo-controlled trials have demonstrated a significant reduction in incontinent episodes and micturition frequency (Jonas et al 1997, Hills et al 1998, Millard et al 1999), whilst the incidence of adverse effects has been shown to be no different to placebo (Rentzhog et al 1998). When compared with oxybutynin in a randomized, double-blind, placebo-controlled, parallel-group study, it was found to be equally efficacious and to have a lower incidence of side-effects, notably dry mouth (Abrams et al 1998). A pooled analysis of the safety, efficacy and acceptability of tolterodine in 1120 patients in four randomized, double-blind, parallel, multicentre trials found that both tolterodine and oxybutynin decreased incontinent episodes significantly, although tolterodine was associated with fewer adverse events, dose reductions and patient withdrawals than oxybutynin (Appell 1997).

Tolterodine has also been developed as an extended-release, once-daily preparation. A double-blind, multicentre trial of 1235 women compared extended-release tolterodine with immediate-release tolterodine and placebo. Whilst both formulations were found to reduce the mean number of urge incontinence episodes per week, the extended-release preparation was found to be significantly more effective (Swift et al 2003). In addition to increased efficacy, extended-release tolterodine has been shown to have better tolerability. In a double-blind, multicentre, randomized placebo-controlled trial of 1529 patients, extended-release tolterodine was found to be 18% more effective in the reduction of episodes of urge incontinence, whilst having a 23% lower incidence of dry mouth (van Kerrebroeck et al 2001).

Extended-release oxybutynin and extended-release tolterodine were compared in the OPERA (Overactive bladder: Performance of Extended Release Agents) study, which involved 71 centres in the USA. Improvements in episodes of urge incontinence were similar for the two drugs, although extended-release oxybutynin was significantly more effective than extended-release tolterodine in reducing the frequency of micturition. Significantly more women taking oxybutynin were also completely dry (23% vs 16.8%; $P = 0.03$), although dry mouth was significantly more common in the oxybutynin group (Diokno et al 2003).

In summary, the available evidence suggests that tolterodine is as effective as oxybutynin; in addition, as it has fewer adverse effects, patient tolerability and compliance are improved.

Trospium chloride

Trospium chloride is a quaternary ammonium compound which is non-selective for muscarinic receptor subtypes and shows low biological availability (Schladitz-Keil et al 1986). It crosses the blood-brain barrier to a limited extent and hence appears to have few cognitive effects (Fusgen and Hauri 2000). A placebo-controlled, randomized, double-blind, multicentre trial has shown trospium to increase cystometric capacity and bladder volume at the first unstable contraction, leading to significant clinical improvement

without an increase in adverse effects over placebo (Cardozo et al 2000). When compared with oxybutynin, it has been found to have comparable efficacy but was associated with a lower incidence of dry mouth (4% vs 23%) and patient withdrawal (6% vs 16%) (Madersbacher et al 1995). At present, trospium chloride appears to be as effective as oxybutynin and may be associated with fewer adverse effects. More recently, an extended-release preparation (Dmochowski et al 2008) has been introduced in the USA and is soon to be licensed in the UK.

Solifenacin

Solifenacin is a potent M_3 receptor antagonist that has selectivity for M_3 receptors over M_2 receptors, and has much higher potency against M_3 receptors in smooth muscle than against M_3 receptors in salivary glands.

The clinical efficacy of solifenacin has been assessed in a multicentre, randomized, double-blind, parallel group, placebo-controlled study of solifenacin 5 mg and 10 mg once daily in patients with overactive bladder (Cardozo et al 2004a). The primary efficacy analysis showed a statistically significant reduction of micturition frequency following treatment with both 5-mg and 10-mg doses compared with placebo, although the largest effect was with the higher dose. In addition, solifenacin was found to be superior to placebo with respect to the secondary efficacy variables of mean volume voided per micturition, episodes of urgency per 24 h, number of incontinence episodes and episodes of urge incontinence. The most frequently reported adverse events leading to discontinuation were dry mouth and constipation. These were also found to be dose related. In order to assess the long-term safety and efficacy of solifenacin (5 mg and 10 mg once daily), a multicentre, open-label, long-term follow-up study has been reported. This was essentially an extension of two previous double-blind, placebo-controlled studies in 1637 patients (Haab et al 2005). Overall, the efficacy of solifenacin was maintained in the extension study with a sustained improvement in symptoms of urgency, urge incontinence, frequency and nocturia over the 12-month study period. The most commonly reported adverse events were dry mouth (20.5%), constipation (9.2%) and blurred vision (6.6%), and these were the primary reason for discontinuation in 4.7% of patients.

More recently, solifenacin 5 mg and 10 mg od have been compared with extended-release tolterodine 4 mg od (Chapple et al 2005). This was a prospective, double-blind, double-dummy, two-arm, parallel-group, 12-week study of 1200 patients with the primary aim of demonstrating non-inferiority of solifenacin to extended-release tolterodine. Solifenacin was not inferior to extended-release tolterodine with respect to change from baseline in the mean number of micturitions per 24 h (reduction of 2.45 micturitions/24 h vs 2.24 micturitions/24 h; $P = 0.004$). In addition, solifenacin resulted in a statistically significant improvement in urgency ($P = 0.035$), urge incontinence ($P = 0.001$) and overall incontinence compared with extended-release tolterodine. In addition, 59% of solifenacin-treated patients who were incontinent at baseline became continent by the study endpoint compared with 49% of patients on extended-release tolterodine ($P = 0.006$).

Darifenacin

Darifenacin is a tertiary amine with moderate lipophilicity, and is a highly selective M_3 receptor antagonist which has been found to have a 5-fold higher affinity for the human M_3 receptor relative to the M_1 receptor (Alabaster 1997).

A review of the pooled darifenacin data from the three Phase III, multicentre, double-blind clinical trials in patients with overactive bladder has been reported in 1059 patients (Chapple et al 2004a). Darifenacin resulted in a dose-related significant reduction in median number of incontinence episodes per week. Significant decreases in the frequency and severity of urgency, micturition frequency and number of incontinence episodes resulting in a change of clothing or pads were also apparent, along with an increase in bladder capacity. Darifenacin was well tolerated. The most common treatment-related adverse events were dry mouth and constipation, although these resulted in few discontinuations. The incidence of central nervous system and cardiovascular adverse events were comparable with placebo.

Fesoterodine

Fesoterodine is a new and novel derivative of 3,3-diphenylpropyl-amine, which is a potent antimuscarinic agent that has recently been developed for the management of overactive bladder. A Phase II dose-finding study was conducted in 728 patients (Chapple 2004b). Fesoterodine 4 mg, 8 mg and 12 mg were all found to show significantly greater decreases in micturition frequency than placebo. The most commonly reported side-effect was dry mouth, with an incidence of 25% in the 4-mg group rising to 34% in the 12-mg group. Subsequently, a Phase III randomized placebo-controlled trial has been reported comparing fesoterodine 4 mg and 8 mg with extended-release tolterodine 4 mg in 1135 patients complaining of overactive bladder (Chapple et al 2006a, 2008). Both doses of fesoterodine demonstrated significant improvements over placebo in reduction of daytime frequency and number of urge incontinence episodes per day, and were found to be superior to tolterodine. The current evidence suggests that fesoterodine may offer some advantages over tolterodine in terms of efficacy and flexible dosing regimens.

Drugs that have a mixed action

Oxybutynin

Oxybutynin is a tertiary amine that undergoes extensive first-pass metabolism to an active metabolite, N-desmethyl oxybutynin (Waldeck et al 1997), which occurs in high concentrations (Hughes et al 1992) and is thought to be responsible for a significant part of the action of the parent drug. It has a mixed action consisting of both an antimuscarinic and a direct muscle relaxant effect in addition to local anaesthetic properties. The latter is important when given intravesically but probably has no effect when given systemically. Oxybutynin has been shown to have a high affinity for muscarinic receptors in the bladder (Nilvebrant et al 1985), and has a higher affinity for M_1 and M_3 receptors than M_2 receptors (Nilvebrant and Sparf 1986).

The effectiveness of oxybutynin in the management of patients with detrusor overactivity is well documented. A

double-blind, placebo-controlled trial found oxybutynin to be significantly better than placebo in improving lower urinary tract symptoms, although 80% of patients complained of significant adverse effects, principally dry mouth or dry skin (Cardozo et al 1987). The antimuscarinic adverse effects of oxybutynin are well documented and are often dose limiting (Baigrie et al 1988), with 10–23% of women discontinuing medication (Kelleher et al 1994a). Using an intravesical route of administration, higher local levels of oxybutynin can be achieved whilst limiting the systemic adverse effects. Using this method, oxybutynin has been shown to increase bladder capacity and lead to a significant clinical improvement (Weese et al 1993). Intravesical administration of oxybutynin is an effective and useful alternative for patients with neurogenic detrusor overactivity who need to self-catheterize or who suffer from 'bypassing' an indwelling catheter (Madersbacher and Jilg 1991). Rectal administration has also been shown to be associated with fewer adverse effects compared with oral administration (Collas and Malone-Lee 1997).

A controlled-release oxybutynin preparation using an osmotic system has been developed which has been shown to have comparable efficacy when compared with immediate-release oxybutynin, and which is associated with fewer adverse effects (Anderson et al 1999). In order to maximize efficacy and minimize adverse effects, alternative delivery systems are currently under evaluation. An oxybutynin transdermal delivery system has been developed and compared with extended-release tolterodine in 361 patients with mixed urinary incontinence. Both agents significantly reduced incontinence episodes, increased volume voided and led to an improvement in QoL compared with placebo. The most common adverse event in the oxybutynin arm was application site pruritus (14%), although the incidence of dry mouth was reduced to 4.1% compared with 7.3% in the tolterodine arm (Dmochowski et al 2003).

More recently, a large prospective, multicentre, randomized, double-blind, placebo-controlled study has been reported investigating the use of oxybutynin gel in the management of overactive bladder in 704 patients (Staskin et al 2009). Overall, there was a significant reduction in urge incontinence episodes in the gel arm compared with the placebo arm (-3.0 vs -2.5 /day; $P < 0.0001$), a significant reduction in daytime frequency (-2.7 , $P = 0.0017$) and an increase in volume voided. When considering adverse events, dry mouth was more common in the treatment arm compared with the placebo arm (6.9% vs 2.8%), and skin site reactions were infrequent in both arms (5.4% and 1.0%, respectively). Consequently, oxybutynin gel may represent an important development over the oxybutynin patch in terms of patient acceptability.

In summary, the efficacy of oxybutynin is well documented, although its clinical usefulness is very often limited by adverse effects. Alternative routes and methods of administration may produce better patient acceptability and compliance.

Propiverine

Propiverine has both antimuscarinic and calcium-channel-blocking actions (Haruno et al 1989). Open studies have demonstrated a beneficial effect in patients with overactive

bladder (Mazur et al 1995) and neurogenic detrusor overactivity (Stoher et al 1999). Dry mouth was experienced by 37% in the treatment group as opposed to 8% in those taking placebo, with dropout rates of 7% and 4.5%, respectively. Propiverine has also been compared with oxybutynin in the management of neurogenic detrusor overactivity in children and adolescents (Madersbacher et al 2009). Overall, propiverine was found to have comparable efficacy to oxybutynin but was better tolerated in terms of adverse effects.

The efficacy and cardiac safety of propiverine has been assessed in a double-blind, multicentre, placebo-controlled, randomized study in 98 elderly patients suffering from urgency, urge incontinence or mixed urge/stress incontinence. After a 2-week placebo run-in period, the patients received propiverine (15 mg tds) or placebo (tds) for a 4-week period. Propiverine caused a significant reduction in micturition frequency and a significant decrease in episodes of incontinence. Only 2% of patients complained of dry mouth, and resting and ambulatory electrocardiograms showed no significant changes (Dorschner et al 2000).

More recently, extended-release propiverine has been introduced and been shown to be as effective as the immediate-release preparation in the management of overactive bladder (Jünemann et al 2006).

Tricyclic antidepressants

These drugs have a complex pharmacological action. Imipramine has antimuscarinic, antihistaminic and local anaesthetic properties. It may increase outlet resistance by peripheral blockage of noradrenaline uptake and it also acts as a sedative. The side-effects are antimuscarinic, together with tremor and fatigue. Imipramine is particularly useful for the treatment of nocturia and nocturnal enuresis (Castleden et al 1981), although other studies have reported little effect (Diokno et al 1972). Other tricyclic antidepressants such as amitriptyline may be substituted for imipramine if specific side-effects are a problem, whilst doxepin has been found to be more potent in its musclotropic relaxant and antimuscarinic activity (Lose et al 1989). A tricyclic antidepressant given prophylactically before sexual intercourse may be of benefit to patients with coital incontinence at orgasm (Cardozo 1988).

In light of relatively poor evidence and the serious adverse effects associated with tricyclic antidepressants, their role in detrusor overactivity remains of uncertain benefit although they are often useful in patients complaining of nocturia or bladder pain.

Calcium-channel antagonists

Contractile activity in the bladder smooth muscle is activated by the movement of extracellular calcium into the cell. Spontaneous and evoked contractile activity are mediated by membrane depolarization and the movement of calcium into the smooth muscle cell through L-type Ca^{2+} channels (Brading 1997). Inhibition of the entrance of Ca^{2+} can prevent spontaneous and evoked contractile activity (Levin et al 1991) with L-type Ca^{2+} blocking agents, such as nifedipine, inhibiting the entry of extracellular calcium.

At present, there is insufficient evidence to suggest that calcium-channel-blocking agents are effective in the treatment of detrusor overactivity, although the development of a selective calcium-channel-blocking agent which eliminates spontaneous contractions without affecting micturition may prove to be of use in the treatment of detrusor overactivity.

Potassium-channel-opening drugs

The opening of K^{+} ion channels in the membrane of the detrusor muscle cell leads to an increase in K^{+} movement out of the cell, resulting in membrane hyperpolarization (Andersson 1997). This reduces the opening probability of ion channels involved in membrane depolarization and hence excitability is reduced (Andersson 1992). These agents act during the filling phase and, whilst abolishing spontaneous detrusor contractions, are not thought to affect normal bladder contractions. Their clinical usefulness is limited by significant cardiovascular effects, with cromakalim and pinacidil being found to be up to 200 times more potent as inhibitors of vascular preparations than of detrusor muscle (Edwards et al 1991). At present, none are commercially available, although the development of subtype-selective drugs may lead to a role in the management of overactive bladder (Lawson 1996).

More recently, newer drugs with K_{ATP} -channel-opening properties have been described (Andersson and Arner 2004). These may be useful for the treatment of bladder overactivity, although there is no evidence at present to suggest that potassium channel openers represent a viable treatment alternative. This is supported by a recently reported randomized, double-blind, placebo-controlled Phase II study evaluating the efficacy and safety of a novel ATP-sensitive potassium channel opener in 299 patients with detrusor overactivity. Whilst treatment was safe and well tolerated, there was no difference over placebo in mean volume voided per micturition and micturition frequency (Chapple et al 2006b).

Antidiuretic agents

Desmopressin

Synthetic vasopressin (desmopressin) has been shown to reduce nocturnal urine production by up to 50%. It can be used for children or adults with nocturia or nocturnal enuresis (Norgaard et al 1989), but must be avoided in patients with hypertension, ischaemic heart disease or congestive cardiac failure (Hilton and Stanton 1982). There is good evidence to show that it is safe to use in the long term (Knudsen et al 1989, Rew and Rundle 1989), and it may be given orally or as a buccal preparation.

Desmopressin has also been used as a 'designer drug' for daytime incontinence (Robinson et al 2004), and also in the treatment of overactive bladder (Hashim et al 2009).

Desmopressin is safe for long-term use; however, the drug should be used with care in the elderly due to the risk of hyponatraemia. The current recommendations are that serum sodium should be checked in the first week following the start of treatment. To identify the safety of desmopressin, a recent systematic review and meta-analysis has been performed of cohort studies and randomized controlled trials

using the oral and intranasal preparations in the treatment of nocturia. In total, 75 papers were identified of which seven reported the incidence of hyponatraemia, giving an overall pooled estimate of 7.6% (95% confidence interval 3.7–15.1). The authors concluded that hyponatraemia is a relatively common adverse event associated with the use of desmopressin, and regular monitoring should be used, particularly in the elderly (Weatherall 2004)

Prostaglandin synthetase inhibitors

Bladder mucosa has been shown to have the ability to synthesize eicosanoids (Jeremy et al 1987), although it is uncertain whether they contribute to the pathogenesis of overactive detrusor contractions. However, they may have a role in sensitizing sensory afferent nerves, increasing the afferent input produced by a given bladder volume. A double-blind controlled study of flurbiprofen in women with detrusor overactivity was shown to have an effect, although it was associated with a high incidence of adverse effects (43%) including nausea, vomiting, headache and gastrointestinal symptoms (Cardozo et al 1980). Indomethacin has also been reported to give symptomatic relief, although the incidence of adverse effects was also high (59%) (Cardozo et al 1980). At present, this evidence does not support the use of prostaglandin synthetase inhibitors in detrusor overactivity.

α -Adrenoreceptor antagonists

The lower urinary tract is innervated by both the parasympathetic and the sympathetic nervous systems, which act via muscarinic and adrenergic receptors, respectively. During the storage phase, continence is maintained by inhibition of the parasympathetic system and by activation of the sympathetic system, which lead to bladder relaxation and urethral sphincter contraction by acting on β_2 - and α -adrenergic receptors, respectively. Conversely, during voiding, the pontine micturition centre inhibits the sympathetic system and activates the parasympathetic system, resulting in urethral relaxation and a sustained bladder contraction.

The adrenergic receptors found at the bladder neck are α_1 adrenergic, and three subtypes have been identified: α_{1A} , α_{1B} and α_{1D} (Malloy et al 1998). Those receptors present in the bladder are predominantly α_{1A} and α_{1D} , whilst α_{1B} receptors are found in the vasculature and are involved in blood pressure control. Consequently, α_1 -adrenergic blocking agents with subselectivity for α_{1A} and α_{1D} may be most useful in the management of lower urinary tract dysfunction, and it has been speculated that the α_{1D} receptor may mediate the overactive symptoms of overactive bladder while the α_{1A} receptor mediates the obstructive symptoms (Schwinn 2000). Anecdotal evidence has demonstrated that tamsulosin, a selective α_1 -adrenoreceptor antagonist, may improve urinary symptoms secondary to detrusor overactivity in men, and it has been used 'off label' in women with symptoms of overactive bladder for some time.

A randomized, double-blind, placebo-controlled study evaluating the efficacy of tamsulosin in the management of women complaining of overactive bladder has been reported recently (Robinson et al 2007). Overall, 364 women (53.3% treatment naïve) were randomized to receive one of four

doses of tamsulosin (0.25 mg, 0.5 mg, 1.0 mg or 1.5 mg), extended-release tolterodine 4 mg or placebo for 6 weeks. The primary efficacy analysis showed that the difference from placebo in the mean number of micturitions/24 h was not statistically significant for tamsulosin 1.5 mg ($P = 0.189$). Interestingly, no statistically significant difference was observed for extended-release tolterodine 4 mg ($P = 0.353$). Similarly, when considering the secondary outcome parameters, there was no statistically significant difference between tamsulosin and placebo. Although women taking extended-release tolterodine 4 mg od demonstrated a consistently greater increase in mean volume voided and consistent decreases in incontinence episodes/24 h, urgency episodes/24 h and episodes of nocturia/24 h, this was not statistically significant compared with placebo. In addition, there was no significant improvement in QoL scores across the treatment groups. The results from this study suggest that α -adrenoreceptor antagonists alone are not clinically useful in the management of overactive bladder in women.

Oestrogens in the Management of Overactive Bladder

Oestrogens have been used in the treatment of urinary urgency and urge incontinence for many years, although there have been few controlled trials to confirm their efficacy. A double-blind, placebo-controlled, crossover study using oral oestril in 34 postmenopausal women produced subjective improvement in eight women with mixed incontinence and 12 women with urge incontinence (Samsicoe et al 1985). However, a double-blind, multicentre study of the use of oestril (3 mg/day) in postmenopausal women complaining of urgency has failed to confirm these findings (Cardozo et al 1993), showing both subjective and objective improvement but not significantly better than placebo. The use of sustained-release 17 β -oestradiol vaginal tablets has also been examined in postmenopausal women with urgency and urge incontinence or a urodynamic diagnosis of sensory urgency or detrusor overactivity. These vaginal tablets have been shown to be well absorbed from the vagina and to induce maturation of the vaginal epithelium within 14 days (Nilsson and Heimer 1992). However, following a 6-month course of treatment, the only significant difference between active and placebo groups was an improvement in the symptom of urgency in those women with a urodynamic diagnosis of sensory urgency (Benness et al 1992). A further double-blind, randomized, placebo-controlled trial of vaginal 17 β -oestradiol vaginal tablets has shown lower urinary tract symptoms of frequency, urgency, urge and stress incontinence to be significantly improved, although no objective urodynamic assessment was performed (Eriksen and Rasmussen 1992). In both of these studies, the subjective improvement in symptoms may simply represent local oestrogenic effects reversing urogenital atrophy rather than a direct effect on bladder function.

A randomized, parallel group, controlled trial has been reported, comparing the oestradiol-releasing vaginal ring with oestril vaginal pessaries in the treatment of postmenopausal women with bothersome lower urinary tract symptoms (Lose and Englev 2000). Low-dose vaginally

administered oestradiol and oestriol were found to be equally efficacious in alleviating lower urinary tract symptoms of urge incontinence (58% vs 58%), stress incontinence (53% vs 59%) and nocturia (51% vs 54%), although the vaginal ring was found to have greater patient acceptability.

A meta-analysis of the use of oestrogen in women with symptoms of overactive bladder has been reported by the Hormones and Urogenital Therapy Committee to try and clarify the role of oestrogen therapy in the management of women with urge incontinence (Cardozo et al 2004b). In a review of 10 randomized placebo-controlled trials, oestrogen was found to be superior to placebo when considering symptoms of urge incontinence, frequency and nocturia, although vaginal oestrogen administration was found to be superior for symptoms of urgency. In those taking oestrogens, there was also a significant increase in first sensation and bladder capacity compared with placebo.

Intravesical Therapy

Capsaicin

Capsaicin is the pungent ingredient found in red chillies and is a neurotoxin of substance-P-containing (C) nerve fibres. Patients with neurogenic detrusor overactivity secondary to multiple sclerosis appear to have abnormal C fibre sensory innervation of the detrusor, which leads to premature activation of the holding reflex arc during bladder filling (Fowler et al 1992). Intravesical application of capsaicin dissolved in 30% alcohol solution can be effective for up to 6 months. The effects are variable (Chandiramani et al 1994) and the long-term safety of this treatment has not yet been evaluated.

Resiniferatoxin

Resiniferatoxin is a phorbol-related diterpene isolated from the cactus, and is a potent analogue of capsaicin that appears to have similar efficacy but fewer side-effects of pain and burning during intravesical instillation (Kim and Chancellor 2000). It is 1000 times more potent than capsaicin at stimulating bladder activity (Ishizuka et al 1995). As with capsaicin, the currently available evidence does not support the routine clinical use of the agents, although they may prove to have a role as an intravesical preparation in neurological patients with neurogenic detrusor overactivity.

Botulinum toxin

Clostridium botulinum produces its effect by production of a neurotoxin; different strains produce seven distinct serotypes designated A–G. All seven have a similar structure and molecular weight, consisting of a heavy and a light chain joined by a disulphide bond (Dolly 1997). They interfere with neural transmission by blocking the calcium-dependent release of neurotransmitter (acetylcholine), causing the affected muscle to become weak and atrophic. The affected nerves do not degenerate, but as the blockage is irreversible, only the development of new nerve terminals and synaptic contacts allows recovery of function.

The use of intravesical botulinum toxin was first described in the treatment of intractable neurogenic detrusor overactivity in 31 patients with traumatic spinal cord injury (Schurch et al 2000). Subsequently, a larger European study has reported on 231 patients with neurogenic detrusor overactivity (Reitz et al 2004). All were treated with 300 units of botulinum-A toxin which was injected cystoscopically into the detrusor muscle at 30 different sites, sparing the trigone. At 12- and 36-week follow-up, there was a significant increase in cystometric capacity and bladder compliance. Patient satisfaction was high, the majority stopped taking antimuscarinic medication and there were no significant complications. More recently, the first randomized placebo-controlled trial has been reported in 59 patients with neurogenic detrusor overactivity (Schurch et al 2005). At 6 months, there was a significant reduction in incontinence episodes in the botox group compared with the placebo group, and a corresponding improvement in QoL evaluation.

Whilst the role of botulinum toxin has been established in the treatment of neurogenic detrusor overactivity, the data regarding its use in intractable idiopathic detrusor overactivity is less robust. A prospective open-label study has recently been reported assessing the use of botulinum-A toxin in both neurogenic (300 units) and idiopathic (200 units) detrusor overactivity in 75 patients (Popat et al 2005). When considering urodynamic outcome parameters in both groups, there was a significant increase in cystometric capacity and a decrease in maximum detrusor pressure during filling in both groups. Clinically, there was also a significant reduction in frequency and episodes of urge incontinence. Interestingly, however, 69% of patients with neurogenic detrusor overactivity required self-catheterization following treatment compared with 19.3% of those with idiopathic detrusor overactivity.

At present, the evidence suggests that intravesical administration of botulinum toxin may offer an alternative to surgery in those women with intractable detrusor overactivity, although the effect is only temporary and there is little long-term data regarding the efficacy and complications associated with repeat injections (Grosse et al 2005).

Behavioural Therapy

As continence is normally learned during infancy, it is logical to suppose that it can be relearned during adult life. Bladder re-education includes bladder drill, biofeedback and hypnotherapy. Bladder discipline was first described as a method of treating urgency incontinence by Jeffcoate and Francis (1966) in the belief that it was exacerbated or even caused by underlying psychological factors. Since then, Frewen (1970) has shown that many women with overactive bladder are able to correlate the onset of their symptoms with some untoward event, which can be identified by taking a careful history. He showed that both inpatient and outpatient bladder drill can be effective forms of treatment for many such women.

The technique for performing inpatient bladder drill has been established by Jarvis (1989) and is shown below. It may be performed either in the inpatient or outpatient setting.

Technique for bladder drill

- Exclude pathology and admit to hospital (if possible).
- Explain rationale to patient.
- Instruct patient to void every 1.5 h during the day (either she waits or is incontinent).
- When 1.5 h is achieved, increase by 30 min and continue with 2-h voiding, etc.
- Allow normal fluid intake (1500 ml/24 h).
- Patient keeps a fluid balance chart.
- Patients meets a successful patient.
- Patient receives encouragement from patients, nurses and doctors.

Jarvis and Millar (1980) performed a controlled trial of bladder drill in 60 consecutive incontinent women with idiopathic overactive bladder. They showed that following inpatient treatment, 90% of the bladder drill group were continent and 83.3% remained symptom-free after 6 months. In the control group, 23.2% were continent and symptom-free due to the placebo effect. Despite the excellent early results, it has been shown that up to 40% of patients relapse within 3 years (Holmes et al 1983).

Biofeedback

Biofeedback is a form of learning or re-education in which the patient is given information about a normally unconscious physiological process in the form of an auditory, visual or tactile signal. The objective effects of biofeedback in the treatment of detrusor overactivity can be recorded on a polygraph trace, but the subjective changes may be difficult to separate from the placebo effect. This technique was originally described by Cardozo et al (1978a). Thirty women aged between 16 and 65 years suffering from idiopathic overactive bladder which was resistant to conventional therapy were treated in two centres (Cardozo et al 1978b). Some 80% of the women were cured or significantly improved subjectively, and 60% were cured or improved objectively. Long-term follow-up revealed a relatively high relapse rate (Cardozo and Stanton 1984) consistent with the long-term effects of bladder drill. Other reports suggest that bladder training with or without biofeedback can be effectively used to treat incontinence due to overactive bladder (Millard and Oldenberg 1983, Burgio et al 1986). However, this type of treatment is time-consuming and requires trained personnel. At present, biofeedback is used almost exclusively to treat children with maladaptive voiding problems.

Hypnotherapy

Hypnotherapy can be used in one of two ways: either symptom removal by suggestion alone, or by attempting to help the patient to disclose hidden emotions or memories which may be pathogenic. Freeman and Baxby (1982) treated 61 women with idiopathic overactive bladder using 12 sessions of hypnosis over a period of 1 month. They achieved an overall improvement rate of over 80%, but unfortunately only nine of the women remained symptom-free at 2-year follow-up (Freeman 1989). Consequently, this type of treatment is not currently employed in the management of overactive bladder.

Acupuncture

Acupuncture is thought to act by increasing levels of endorphins and enkephalins in the cerebrospinal fluid. Enkephalins are known to inhibit detrusor contractility *in vitro* (Klarskov 1987). Naloxone, an opiate antagonist, conversely causes decreased bladder capacity and increased detrusor pressure (Murray and Feneley 1982). Several studies have shown symptomatic improvement (Philp et al 1988) or decreased frequency and urinary leakage (Pigne et al 1985) in patients with overactive bladder treated with acupuncture. Gibson et al (1990) utilized infra-red low-power laser on acupuncture points with initial success, but unfortunately there was a high relapse rate at 6 months. Acupuncture is as effective as oxybutynin in the treatment of symptoms associated with idiopathic low compliance, and it is acceptable to patients but time-consuming for the operator (Kelleher et al 1994b). Acupuncture has also been compared with placebo treatment in a randomized controlled trial of 85 women (Emmons and Otto 2005). Overall, there was a greater reduction in incontinence episode frequency in the acupuncture arm compared with the placebo arm (59% vs 40%; $P > 0.05$), with a significant reduction in frequency (14%; $P = 0.013$) and improvement in QoL ($P < 0.001$).

All forms of bladder retraining in the treatment of overactive bladder are advantageous because there are few unpleasant side-effects and no patient is ever made worse. Mild-to-moderate overactive bladder can be cured or improved significantly by re-educating the bladder. However, the relapse rate is very high, and although this type of treatment avoids the morbidity associated with surgery and the side-effects of drug therapy, it requires skilled personnel and is time-consuming for both the patient and the operator. A meta-analysis has concluded that bladder retraining is more effective than placebo and medical therapy, although there is insufficient evidence to support the effectiveness of electrical stimulation and too few studies to evaluate the effect of pelvic floor exercises and biofeedback in women with urinary urge incontinence (Berghmans et al 2000).

Neuromodulation

Sacral neuromodulation

Stimulation of the dorsal sacral nerve root using a permanent implantable device in the S3 sacral foramen has been developed for use in patients with overactive bladder and neurogenic detrusor overactivity. Prior to implantation, temporary cutaneous sacral nerve stimulation is performed to check for a response; if successful, a permanent implant is inserted under general anaesthesia. Initial studies in patients with overactive bladder refractory to medical and behavioural therapy have demonstrated that after 3 years, 59% of 41 urinary urge incontinent patients showed greater than 50% reduction in incontinence episodes, with 46% of patients being completely dry (Seigel et al 2000).

Whilst neuromodulation remains an invasive and expensive procedure, it does offer a useful alternative to medical and surgical therapies in patients with severe, intractable overactive bladder prior to considering reconstructive

surgery, although technical failure may often necessitate surgical revisions.

Peripheral neuromodulation

Stimulation of the posterior tibial nerve in patients with urge incontinence was first reported in 1983 (McGuire et al 1983), and has also been proposed for pelvic floor dysfunction (Stoller 1999). The tibial nerve is a mixed nerve containing L4–S3 fibres and originates from the same spinal cord segments as the innervation to the bladder and pelvic floor. Consequently, peripheral neural modulation may have a role in the management of urinary symptoms.

In a prospective multicentre study, 35 patients with urge incontinence underwent 12 weekly sessions of posterior tibial nerve stimulation (PTNS), with 70% of patients reporting a greater than 50% reduction in urinary symptoms and 46% being completely cured (Vandoninick et al 2003). More recently, a prospective, randomized, multicentre North American study has been reported comparing PTNS with extended-release tolterodine 4 mg in 100 patients. Overall, there was an improvement in 75% of patients with PTNS compared with 55.8% with extended-release tolterodine, and there was a significant improvement in QoL in both groups (Peters et al 2008).

Consequently, peripheral neuromodulation may offer an alternative therapeutic option for those patients with intractable overactive bladder who have failed to respond to medical therapy.

Surgery

Approximately 10% of women with overactive bladder remain refractory to medical and behavioural therapy, and may be considered for surgery. Various different surgical techniques have been developed, although augmentation is currently the most commonly performed technique using a clam cystoplasty, or autoaugmentation using detrusor myectomy.

Clam cystoplasty

In clam cystoplasty (Bramble 1990, Mast et al 1995), the bladder is bisected almost completely and a patch of gut (usually ileum) equal in length to the circumference of the bisected bladder (approximately 25 cm) is sewn in place. This often cures the symptoms of overactive bladder (McRae et al 1987) by converting a high-pressure system into a low-pressure system, although inefficient voiding may result. Patients have to learn to strain to void or may have to resort to clean intermittent self-catheterization, sometimes permanently. In addition, mucus retention in the bladder may be a problem, but this can be partially overcome by ingestion of 200 ml of cranberry juice each day (Rosenbaum et al 1989) in addition to intravesical mucolytics such as acetylcysteine. The chronic exposure of the ileal mucosa to urine may lead to malignant change (Harzmann and Weckerman 1992). There is a 5% risk of adenocarcinoma arising in ureterosigmoidostomies, where colonic mucosa is exposed to N-nitrosamines found in both urine

and faeces, and a similar risk may apply to enterocystoplasty. Biopsies of the ileal segment taken from patients with clam cystoplasties show evidence of chronic inflammation of villous atrophy (Nurse and Mundy 1987), and diarrhoea due to disruption of the bile acid cycle is common (Barrington et al 1995). This may be treated using cholestyramine. In addition, metabolic disturbances such as hyperchloraemic acidosis, B₁₂ deficiency and, occasionally, osteoporosis secondary to decreased bone mineralization may occur.

Detrusor myectomy

Detrusor myectomy offers an alternative to clam cystoplasty by increasing functional bladder capacity without the complications of bowel interposition. In this procedure, the whole thickness of the detrusor muscle is excised from the dome of the bladder, thereby creating a large bladder diverticulum with no intrinsic contractility (Cartwright and Snow 1989). Whilst there is a reduction in episodes of incontinence, there is little improvement in functional capacity and thus frequency remains problematic (Kennelly et al 1994, Snow and Cartwright 1996).

Urinary diversion

As a last resort, for those women with severe overactive bladder or neurogenic detrusor overactivity who cannot manage clean intermittent catheterization, it may be more appropriate to perform a urinary diversion. Usually, this will utilize an ileal conduit to create an incontinent abdominal stoma for urinary diversion. An alternative is to form a continent diversion using the appendix (Mitrofanoff) or ileum (Koch pouch), which may then be drained using self-catheterization.

National Institute for Health and Clinical Excellence Guidelines

The medical management of overactive bladder has been reviewed recently by the National Institute for Health and Clinical Excellence (2006). In the first instance, bladder retraining lasting for a minimum of 6 weeks should be offered to all women with mixed or urge incontinence. In those women who do not achieve satisfactory benefit from bladder retraining alone, an antimuscarinic agent in addition to bladder retraining should be considered.

When considering drug therapy, immediate-release non-proprietary oxybutynin should be offered to women with overactive bladder or mixed urinary incontinence as first-line drug treatment if bladder retraining has been ineffective. If immediate-release oxybutynin is not well tolerated, darifenacin, solifenacin, tolterodine, trospium or an extended-release or transdermal formulation of oxybutynin should be considered as alternatives. In addition, women should be counselled regarding the adverse effects of antimuscarinic drugs.

Propiverine should be considered as an option to treat the frequency of micturition, but this is not recommended for

the treatment of urinary incontinence. Flavoxate, propantheline and imipramine should not be used for the treatment of overactive bladder. Whilst desmopressin may be considered specifically to reduce nocturia in women, this is currently outside the marketing authorization; hence, informed consent must be obtained.

When considering the role of oestrogens, the recommendations are that systemic hormone replacement therapy should not be recommended, although intravaginal oestrogens are recommended for the treatment of overactive bladder in postmenopausal women with urogenital atrophy.

Conclusion

Overactive bladder is a common and distressing condition, affecting people of all ages. It is characterized by multiple symptoms which, although not life-threatening, may cause much embarrassment and a very restricted lifestyle. Lack of understanding of the underlying pathology of overactive bladder is reflected in the numerous different methods of treatment which are currently employed, none of them wholly satisfactory. Conventional bladder neck surgery is not useful in the treatment of overactive bladder unless there is

concomitant urethral sphincter incompetence; therefore, it is important to make an accurate diagnosis before treatment is commenced.

Behavioural intervention seems to be the best type of treatment of idiopathic overactive bladder because it may produce a permanent cure without any significant morbidity or side-effects. However, the majority of patients are still treated with drug therapy, which they may need to take indefinitely as symptoms usually return once the tablets are discontinued. Surgical procedures such as augmentation cystoplasty are reserved for women with severe symptoms in whom other forms of treatment have been tried and failed.

Fortunately, overactive bladder is a disease of spontaneous exacerbations and remissions. Therefore, short courses of drug therapy, when symptoms are at their worst, may be sufficient for the sufferer to maintain a normal lifestyle. Although it is rare to cure a patient completely with any form of treatment, most can have their symptoms reduced significantly. The elucidation of the patient's main complaints is therefore of great importance. As the pathophysiology of the condition becomes clearer, leading to the development of new drugs offering greater efficacy and improved compliance, significant advances in the management of overactive bladder can be expected.

KEY POINTS

1. Overactive bladder is a symptomatic diagnosis.
2. Detrusor overactivity is a urodynamic-based diagnosis.
3. Detrusor overactivity may occur in 10% of the normal population and be asymptomatic.
4. The incidence of overactive bladder increases with age.
5. Whilst neurogenic detrusor overactivity is associated with neurological disease, the cause of idiopathic detrusor overactivity remains unknown.
6. The diagnosis of overactive bladder can be suggested by symptoms, but a diagnosis of detrusor overactivity can only be confirmed on cystometry.
7. Bladder retraining and behaviour modification are important primary treatments which can be augmented by antimuscarinic drug therapy.
8. Most antimuscarinic drugs need to be given at a dosage which will produce parasympathetic side-effects.
9. Mild overactivity can be cured or improved by bladder retraining but the relapse rate is high.
10. Where detrusor overactivity and urethral sphincter incompetence coexist (mixed incontinence), it is preferable to treat the detrusor overactivity prior to considering continence surgery.

Appendix

Levels of evidence

- I Systematic review of all relevant randomized controlled trials
- IIA One randomized controlled trial — low probability of bias and high probability of causal relationship
- IIB One randomized controlled trial
- IIIA Well-designed controlled trials (no randomization)
- IIIB Cohort or case-control studies
- IIIC Multiple time series or dramatic results in uncontrolled experiments
- IV Expert opinion (traditional use)

Grades of recommendations

- A A systematic review of randomized controlled trials or a body of evidence consisting principally of studies rated as 1 directly

applicable to the target population and demonstrating overall consistency of results

- B A body of evidence including studies rated as 2A directly applicable to the target population and demonstrating overall consistency of results or
Extrapolated evidence from studies rated as 1
- C A body of evidence including studies rated as 2B directly applicable to the target population and demonstrating overall consistency of results or
Extrapolated evidence from studies rated as 2
- D Evidence level 3 or 4 or
Extrapolated evidence from studies rated as 2

Introduction

Normal voiding occurs when tension receptors in the bladder sense fullness and stimulate a sacral reflex of somatically mediated relaxation of the pelvic floor and urethra, and parasympathetically mediated detrusor contraction. In the adult, this simple reflex is under voluntary control via a set of complex pathways which run from the cerebral cortex to the pontine micturition centre and the sacral spinal cord via the lateral spinothalamic tracts and the posterior columns. The sacral micturition centre is located at S2–4 level. Peripheral innervation to the bladder and urethral sphincter is supplied by the pelvic, hypogastric and pudendal nerves.

Imaging studies on normal women have shown that the bladder base and the upper urethra move downwards, the lower urethra remains fixed, the bladder as a whole becomes more ovoid in shape, the posterior urethrovesical angle becomes obliterated, funnelling occurs at the bladder neck, and the whole urethra dilates as the fluid passes.

Studies on detrusor pressure during voiding in normal women suggest that most void with a detrusor contraction greater than 15 cmH₂O (mean detrusor pressure at maximum flow 23–28 cmH₂O, maximum detrusor pressure 20–36 cmH₂O) (Figure 54.1). Detrusor pressure during voiding is generally lower in women than in men. A few normal women have been reported to void with a low pressure detrusor contraction of less than 15 cmH₂O, but no normal women void with no contraction at all; such an event may indicate low urethral closure pressure.

There are variations in the way that women void. Some women, in addition to pelvic relaxation and detrusor contraction, may strain by an unconscious but sustained Valsalva manoeuvre (Figure 54.2). The contribution of

abdominal pressure to the voiding process varies considerably between individuals and within the same individual during consecutive voids.

The 'normal' voiding curve in women has a single peak, with a fast crescendo and a relatively slow diminuendo, with minimal fluctuations. However, an interrupted pattern can be seen repeatedly in a minority of normal women. Studies of flow rates suggest that most normal women void with a peak flow rate greater than 15 ml/s, with mean values of 23–27 ml/s (Figure 54.1). Peak flow rate values are generally higher in women than in men. The main variable affecting flow rates in normal women is bladder volume, with greater flow rates seen with increasing volumes. Parity, weight and height have no influence on flow rates.

In this chapter, deviations from this pattern of normality will be presented and discussed, particularly with reference to clinical situations relevant to urogynaecological practice.

Definitions

Voiding difficulty

A joint International Urogynecological Association/International Continence Society (ICS) Report on terminology for female pelvic floor dysfunction defines 'voiding difficulty' as 'abnormally slow and/or incomplete micturition' (Haylen et al 2010). The diagnosis is obtained by symptoms (see below) and urodynamic investigations, and should be based on repeated measurements to confirm abnormality.

Abnormally slow urine flow rates, as determined by uroflowmetry, are best referenced to nomogram charts which provide a range of normality for urinary flow rates in relation

Figure 54.1 Normal voiding.

Figure 54.2 Voiding with detrusor contraction supplemented with abdominal straining.

to volume voided; abnormal flow is defined as flow under the 10th centile (Haylen et al 1989). To encourage the use of these charts, a larger version of the original charts has been republished recently (Haylen et al 2008a).

Abnormally high postvoid residuals (i.e. volume left in the bladder at the completion of micturition) depend on the method used for measurement and the timing of the measurement after micturition, taking into account renal input of 1–14 ml urine/min (Haylen et al 2010).

Upper limits of postvoid residuals of 30 ml (using immediate ultrasound assessment) and 50–100 ml (using urethral catheterization) have been proposed (Haylen et al 2010).

Acute retention of urine

This is defined as a generally, but not always, painful, palpable or percussable bladder, when the patient is unable to pass any urine when the bladder is full (Haylen et al 2010).

Chronic retention of urine

This is defined as a non-painful bladder where there is a chronic high postvoid residual (Haylen et al 2010).

Incidence

Depending on definition and type of clinic, voiding difficulty in women presenting to a urology or urogynaecology clinic has a variable prevalence ranging from 14% (when using a strict definition based on multiple variables including low flow, high pressure and increased postvoid residual) (Massey and Abrams 1988) to 39% (using a postvoid residual of 30 ml or more) (Haylen et al 2007).

Symptoms and Clinical Effects

When present, symptoms of voiding difficulty are non-specific and include hesitancy, slow stream, straining to void, feeling of incomplete bladder emptying, spraying, need to immediately revoid, position-dependent micturition (e.g. leaning forwards or backwards, semi-erect), and dysuria.

Women with voiding dysfunction may present with urinary incontinence; this is often unconscious leakage due to 'overflow incontinence', although this term lacks a precise definition. Recurrent urinary tract infections (UTI) and 'irritative' bladder symptoms such as frequency and urgency, with and without coexistent detrusor overactivity, may be reported.

Inability to void usually leads to prolonged use of urinary catheters and an increased incidence of UTI. The risk of acquiring bacteriuria relates to the duration of catheterization, and ranges from 4% to 7.5%/day over the first 10 days of catheterization (Schaeffer 1986). The majority of patients on long-term clean catheterization have bacteriuria, and about one-third of them require intermittent treatment with antibiotics due to symptomatic infection (Lapides et al 1976). Catheter-related UTI is an important cause of hospital-acquired infections, morbidity (e.g. pyelonephritis) and, in the elderly, mortality.

When voiding difficulty develops after surgery, hospital stay is often prolonged. When patients are discharged with a catheter, daily nursing care in the community is required. This can lead to an escalation in costs.

In the long term, inability to void may lead to profound alterations in quality of life and have serious psychological effects.

Causes

The causes of voiding difficulty are shown in Box 54.1.

Effects of age on voiding function

The incidence of voiding dysfunction in women increases with age (Haylen et al 2008b), and the process of ageing may decrease detrusor contractility and increase urethral rigidity.

Urodynamic studies have shown that both peak flow rate and detrusor pressure during voiding decrease with advancing age. Older women are also more likely to strain abdominally during voiding and to have higher residual urine volumes (Malone-Lee and Wahedna 1993).

With advancing age, anatomical changes occur in the bladder wall leading to reduced bladder contractility (e.g. increased collagen content in the detrusor muscle, reduction in the number of cholinergic nerves, dedifferentiation of detrusor muscle cells). Changes leading to urethral atrophy and increased rigidity also occur (e.g. reduced striated muscle and vessel content, increased connective tissue).

Box 54.1 Causes of voiding difficulty

- Age
- Postoperative: pelvic surgery, incontinence surgery, prolapse surgery
- Post partum
- Neurological disease
- Psychogenic
- Pelvic organ
- Prolapse
- Idiopathic bladder neck obstruction
- Bladder overdistension/infrequent voiding
- Drugs
- Infection
- Pelvic mass
- Urethral or bladder pathology
- Detrusor myopathy/acontractility
- Iatrogenic

While it is not clear whether voiding dysfunction is due to 'normal' ageing of the lower urinary tract or to the presence of disease processes, age is the only risk factor that has been consistently associated with the development of postoperative voiding dysfunction after anti-incontinence surgery. Increased urethral rigidity may increase the likelihood of causing obstruction, and reduced detrusor contractility may reduce the ability to cope with it.

It is not clear whether the menopause has an effect on voiding which is distinct from age. There are no studies showing that the menopause *per se* has a deleterious effect on voiding function. However, the distal urethra is oestrogen dependent and therefore susceptible to postmenopausal atrophic changes; the reduction in urethral functional length seen after the menopause is likely to be a manifestation of this process. There is evidence that these changes are more pronounced in a minority (18%) of postmenopausal women (Smith 1972). These women may have increased urethral rigidity and may be predisposed to the development of voiding dysfunction should they undergo pelvic or anti-incontinence surgery.

Postoperative voiding dysfunction

Pelvic surgery

Temporary voiding difficulty is commonly observed after pelvic surgery. In the immediate postoperative period, many reversible factors are likely to play a role. Atropine and other anaesthetic reversal agents with anticholinergic effects (some with a half-life of 3–4 days) may reduce detrusor contractility. Opiates might reduce bladder sensation, pain might inhibit perineal relaxation, and bladder overfilling might depress detrusor contractility. In addition, bruising and oedema can also depress bladder contractility and cause temporary obstruction. Spinal anaesthesia depresses voiding function for up to 4–8 h, depending on whether short- or long-acting agents are used. Epidural anaesthesia may depress voiding function for 14–16 h, especially when supplemented by opioids in the epidural space.

With regards to specific procedures, clinical and urodynamic studies have found no evidence of increased voiding dysfunction in the short term after vaginal hysterectomy with anterior colporrhaphy performed at the same time (Stanton et al 1982), and after abdominal hysterectomy (Wake 1980). Also, no differences in bladder function were observed in a randomized study comparing total with subtotal hysterectomy (Thakar et al 2002). However, a history of previous hysterectomy has been associated with increased risk of voiding difficulty, possibly due to nerve dysfunction (Dietz et al 2002).

Extensive pelvic surgery might lead to denervation and prolonged or permanent voiding difficulty. Radical hysterectomy has been shown to lead to prolonged voiding difficulty in one-quarter of patients (Scotti et al 1986) due to neuropathic dysfunction.

Surgery for stress incontinence

Surgery for stress incontinence is an important cause of impaired bladder emptying in women. There is no universally accepted definition of voiding dysfunction after

Figure 54.3 Voiding without detrusor contraction (pelvic relaxation alone).

incontinence surgery, and voiding function is often reported empirically in studies (e.g. as 'time required for resumption of voiding' or 'time of catheter removal'). In most cases, postoperative voiding problems are short term, but they can persist in the long term and lead to profound alterations in quality of life. Prolonged or 'late' voiding dysfunction after incontinence surgery may also affect patients who did not have 'early' dysfunction in the immediate postoperative period. This may be due to failure to obtain an early diagnosis, progressive effects of scarring or onset of new pathology.

Women with stress incontinence may already have some impairment of voiding function, which may make them more vulnerable to the obstructive effects of surgery. This is suggested by differences in several urodynamic (voiding) variables noted in these women. For example, in contrast with normal women, women with stress incontinence are more likely to strain during voiding, and to initiate voiding with a Valsalva manoeuvre as opposed to pelvic relaxation. They also void with significantly lower detrusor pressures, and up to 15% have been shown to void without a contraction (Figure 54.3; Karram et al 1997). It is not clear whether this is due to the lower mean urethral pressure of women with urodynamic stress incontinence, or whether there is a real impairment of detrusor muscle function in these women.

Postoperative voiding disorders have been reported to occur after most operations for stress incontinence. Prolonged voiding dysfunction is uncommon after urethral injectables, although an incidence of 5% has been reported (Khullar et al 1997). The colposuspension operation leads to postoperative voiding dysfunction in a mean of 12.5% of patients (Jarvis 1994). Laparoscopic and open colposuspension have the same incidence of postoperative voiding difficulty (Carey et al 2006). Results of a randomized study comparing the tension-free vaginal tape (TVT) procedure with colposuspension suggest that the incidence of voiding difficulty at 6 months is similar after both operations (7%), although patients experience earlier voiding in the immediate postoperative period after the TVT procedure (Ward and Hilton 2002). After the TVT procedure, 11% of women have been reported to need a catheter for more than 24 h (Vervest et al 2007), with only 2% needing

tape release for prolonged difficulty (Kuuva and Nilsson 2002, Karram et al 2003, Vervest et al 2007). The transobturator tape (TOT) procedure has been shown to have a lower incidence of postoperative voiding difficulty than the TVT, possibly as it is less obstructive (Latthe et al 2007).

Voiding difficulty after incontinence surgery is multifactorial. In addition to temporary factors, as detailed above, permanent factors might be relevant from the outset. Some factors are obstructive and relate to the operative technique (e.g. excessive tape tension when using midurethral slings, or excessive bladder neck elevation at colposuspension), while others relate to the patient and her capacity to deal with obstruction (e.g. age and poor detrusor contractility). An intrinsically weak detrusor may be unable to cope with even the slightest increase in outflow resistance.

Prolapse surgery

Short-term voiding difficulty is common after vaginal surgery for prolapse. In a large series of women undergoing such surgery, urinary retention (defined as a postvoid residual of ≥ 200 ml after removal of the catheter the day after the operation) occurred in 29% of women, with 9% experiencing retention for more than 3 days (Hakvoort et al 2009). In another study, 11% of women required catheterization at home after discharge from hospital (Vierhout 1998). However, no patients experienced long-term voiding difficulty (Vierhout 1998, Hakvoort et al 2009). Performing a levator muscle plication (as part of a posterior colporrhaphy) and a Kelly suburethral plication (as part of an anterior colporrhaphy) can increase the risk of postoperative retention (Hakvoort et al 2009).

A policy of early catheter removal, the day after vaginal surgery seems preferable to routine prolonged catheterization (4 days) as it is associated with a lower incidence of UTI and a shorter duration of hospital stay (Hakvoort et al 2004). However, early catheter removal increases the risk of recatheterization: 40% in the 'early' removal group vs 9% in the 'late' removal group (Hakvoort et al 2004). Prolonged catheterization may therefore be preferable in individual cases when there is an increased risk of postoperative voiding difficulty.

Postpartum voiding difficulty

Prolonged voiding difficulty in the postpartum period requiring self-catheterization is uncommon and has been reported to occur after less than 1% of deliveries (Glavind and Bjørk 2003). However, when using strict criteria [similar to those proposed recently by the International Urogynecological Association/International Continence Society (2010)], up to 43% of women have been shown to have some degree of voiding difficulty after delivery (Ramsay and Torbet 1993). Recognized risk factors for voiding difficulty in the immediate postpartum period are primiparity, instrumental delivery, epidural analgesia, prolonged labour, perineal trauma and poor bladder management resulting in overdistension. In addition to temporary factors (e.g. epidural, morphine, anaesthetic), other factors causing prolonged voiding dysfunction may be present (e.g. trauma to the bladder, pelvic floor muscles and nerves).

Neurological disease

The effects of neurological disease on bladder function and the upper renal tracts depend on the site of the lesion(s). Interruption of the mainly inhibitory pathways from the cerebral cortex to the pontine micturition centre (e.g. stroke, tumour, trauma, Parkinson's disease) is likely to result in uninhibited detrusor contraction and incontinence. Interruption of the neural pathways from the pontine to the sacral centres [e.g. spinal cord injury, multiple sclerosis (MS)] may also lead to uninhibited contractions (neurogenic detrusor overactivity) with or without failure of relaxation of the urethral sphincter (detrusor sphincter dyssynergia). Interruption of the sacral reflex arc (e.g. diabetic neuropathy, low spinal cord tumours, lumbar disc prolapse) may lead to acontractility of the detrusor muscle (atonic bladder), with voiding difficulty and retention.

Impaired voiding function (e.g. detrusor sphincter dyssynergia) can potentially lead to high detrusor pressure, reflux and upper tract changes (e.g. hydronephrosis), resulting in renal failure.

Specific neurological conditions are discussed below.

Lumbar intervertebral disc prolapse

Lumbar disc prolapse is extremely common, with approximately 30% of adults without back pain having evidence of a protruded disc on magnetic resonance imaging (MRI) (Jarvik and Deyo 2007). In patients with symptomatic lumbar disc prolapse, urodynamic studies have shown voiding difficulty due to reduced detrusor contractility in approximately one-quarter of cases (Bartolin et al 1998). The most common sites of lumbar disc prolapse are L4–5 and L5–S1. Compression occurs more often in a posterolateral direction but may also be central. Patients may report a long history of low back pain, or voiding difficulty may be the first or only symptom. Compression of the sacral nerves can lead to cauda equina syndrome, characterized by voiding difficulty, saddle anaesthesia, bilateral sciatica and low back pain. Physical examination in these cases shows reduced sensation in the saddle and perianal area. If nerve compression is seen on MRI, urgent surgical treatment, usually laminectomy, is indicated. Despite this, voiding

function often fails to improve after surgery (Bartolin et al 1999).

The lithotomy position commonly used to perform gynaecological procedures can potentially precipitate lumbar disc prolapse (Choudhari et al 2000). It has been suggested that flexion and hyperabduction of the hips may stretch nerve roots already compromised by a partial 'occult' disc prolapse (Choudhari et al 2000). When no other explanation can be found, this possibility should always be considered and investigated by MRI should a patient develop prolonged voiding difficulty after a gynaecological procedure.

Parkinson's disease

Parkinson's disease typically affects the basal ganglia where loss of the substantia nigra results in dopamine deficiency. This has a profound effect on the extrapyramidal system. However, other 'Parkinsonian' syndromes (e.g. multiple system atrophy) are associated with lesions in other areas of the central and peripheral nervous systems. The majority of women with these conditions have urinary symptoms. These may be due to detrusor overactivity (more common in Parkinson's disease) or detrusor underactivity (more common in multiple system atrophy). Coexistent urethral sphincter dysfunction is common, with poor sphincter coordination with voiding (more frequent in Parkinson's disease) and intrinsic sphincter deficiency (more frequent in multiple system atrophy).

Multiple sclerosis

MS plaques are common along the spinal cord in a variety of locations. Lower urinary tract dysfunction is therefore present in the majority of women affected by MS. Reported symptoms include frequency, urgency, urge incontinence and voiding difficulty. In a small minority of women, bladder symptoms are the presenting manifestation of the disease.

Functional effects are various and may change during the course of the disease. They include neurogenic detrusor overactivity (with or without detrusor sphincter dyssynergia) and, less frequently, detrusor acontractility.

In the past, the death of MS patients could often be attributed to urological complications (e.g. upper tract changes and infection). Prompt recognition and management of voiding dysfunction in these patients has made this a rare occurrence.

Diabetes

Bladder dysfunction is relatively common in diabetic women and has been reported in 22% of women attending a diabetic clinic (Yu et al 2004). It is due to peripheral and autonomic neuropathy, leading to reduced bladder sensation and contractility. The classical features of diabetic cystopathy are an insidious onset with impaired bladder sensation and progressive voiding difficulty. Recurrent UTIs are common. Detrusor overactivity also occurs frequently, perhaps as a sign of cortical or spinal involvement.

Psychological factors

Psychological factors may cause or contribute to voiding dysfunction by centrally mediated, unconscious inhibition

of either detrusor contraction, pelvic floor relaxation or both. This is confirmed by the inability of many individuals to void when there is a lack of privacy (so-called 'paruresis' or 'shy bladder syndrome').

True psychogenic urinary dysfunction is uncommon but is usually accompanied by obvious psychological or psychiatric features, such as conversion disorder (hysteria) and anxiety. There is often a precipitating stressful 'trigger' event. A history of sexual abuse may be present.

Idiopathic bladder neck obstruction

This is a poorly defined, infrequent condition characterized by failure of the urethral sphincter to relax, and possibly hypertrophy, with urodynamic variables showing high pressure and low flow in the absence of neurological or urological abnormality. It was originally described in a cohort of young women with polycystic ovaries and voiding difficulty (Fowler's syndrome; Fowler et al 1988). The cause is unknown. There is a suggestion that α -blockers may be beneficial in these patients (Athanasopoulos et al 2009).

Pelvic organ prolapse

Although the majority of women with pelvic organ prolapse (POP) can void effectively, there is an association between POP and voiding dysfunction (Coates et al 1997, Haylen et al 2008b). Symptoms of voiding difficulty (Digesu et al 2005) and high postvoid residuals (Haylen et al 2008b) are more common in women with POP. Urodynamic evidence of voiding difficulty has been found to correlate with POP severity, with high-grade cystocele being the most common anatomical defect leading to voiding difficulty (Romanzi et al 1999). Severe prolapse of the posterior vaginal compartment has also been shown to have a negative effect on voiding function (Myers et al 1998, Dietz et al 2002). Kinking of the urethra (by a prolapse of the anterior vaginal compartment) or direct pressure on the urethra and bladder neck (by a prolapsing uterus or posterior vaginal compartment) are possible mechanisms of obstruction, leading to voiding difficulty.

Overactive bladder symptoms and occult stress incontinence often coexist with voiding difficulty in women with pelvic organ prolapse (Romanzi et al 1999).

Prolapse correction with a pessary has been shown to improve voiding function in the majority of women with both pathologies (Romanzi et al 1999). In most women with severe prolapse and voiding difficulty, corrective surgery restores voiding successfully (Fitzgerald et al 2000, Liang et al 2008).

Bladder overdistension

Bladder overdistension can be iatrogenic (i.e. the result of a delay in the diagnosis of voiding difficulty, with delayed catheterization), and this event *per se* can also lead to further and sometimes prolonged voiding difficulty. Studies of bladder function after overdistension, mostly in animal models and in men with retention associated with prostatic hypertrophy, have shown reduced bladder contractility. This is probably due to denervation, stretch damage to the detrusor muscle, and metabolic injury due to ischaemia and

reperfusion. The time of recovery after such injury has not been investigated in women, but is likely to depend on the cause of the bladder overdistension, the amount of fluid retained and the time of retention.

Infrequent voiding can lead to chronic bladder overdistension and voiding difficulty, but evidence for this is lacking.

Others

In addition to anaesthetics and analgesics, drugs with anticholinergic action (e.g. antidepressants, antipsychotics, oxybutinin etc.) can potentially worsen voiding function and precipitate retention in individual cases. However, antimuscarinic therapy was not found to worsen voiding function in a series of women with overactive bladder and mild voiding difficulty (postvoid residuals of ≥ 100 ml) (Robinson et al 2003).

Intravesical Botox for treatment of the overactive bladder has been shown to increase postvoid residuals, but retention requiring self-catheterization is uncommon (Duthie et al 2007), with one large series reporting an incidence of 4% (Schmid et al 2006).

Pelvic masses (e.g. fibroids, retroverted gravid uterus, ovarian cysts, faecal impaction, haematocolpos) can cause voiding difficulty due to a direct pressure effect.

Infections (e.g. urethritis, cystitis, vulvovaginitis) can cause acute retention due to inflammation and pain, with genital herpes and sacral herpes zoster possibly also due to nerve impairment.

Urethral pathology, other than the effects of incontinence surgery (e.g. tumours, strictures, diverticulae, foreign bodies and stones), may rarely cause voiding difficulty.

Lichen's sclerosis can cause complete fusion of the labia and closure over the urethral meatus, resulting in voiding difficulty.

Investigations

Uroflowmetry

In practical terms, most women with voiding difficulty require simple flow studies with measurement of post void residual urine with catheters or ultrasound. Features include changes in the normal bell-shaped curve, with intermittent or multiple peaked flow (suggestive of abdominal straining or unsustained bladder contractions) (Figure 54.4), and/or low flow rates. Although there are no clear-cut values, low peak flow rates of less than 12–20 ml/s have been used traditionally, with voided volumes of 150–200 ml. Postvoid residual urine volumes of more than 50–100 ml were arbitrarily considered abnormal.

It is now suggested that volume-specific nomograms should be used, with abnormal flow defined as under the 10th centile (International Urogynecological Association/International Continence Society 2010). Repeated measurements are necessary to confirm abnormality.

Upper limits of postvoid residuals of 30 ml using immediate ultrasound assessment and 50–100 ml using urethral catheterization have been proposed, taking into account renal input of 1–14 ml urine/min (International Urogynecological Association/International Continence Society 2009).

Figure 54.4 Voiding difficulty with obstruction after colposuspension. Note prolonged interrupted flow.

An alternative screening method, using a peak flow rate of less than 15 ml/s and/or postvoid residual urine volume greater than 50 ml with a minimum total bladder volume of 150 ml before voiding, has been shown to correlate well with the Liverpool nomograms (Haylen et al 1989), and could be used if nomogram charts are not available (Costantini et al 2003).

Uroflowmetry, however, is only a screening test. More complex urodynamic studies are advisable in the presence of coexistent overactive bladder symptoms, neurological disease or when the cause of voiding difficulty is unclear.

Pressure–flow studies

The assessment of voiding difficulty in the female, as in the male, relies on pressure–flow studies. In men, low flow in the presence of high detrusor pressure usually signifies obstruction (using nomograms), but this is less clear in women.

In an attempt to obtain cut-off values for the definition of obstruction in women, urodynamic studies have been performed in obstructed patients and compared with controls. For example, in repeated non-invasive flow studies, the presence of a peak flow rate of less than 12 ml/s, with a detrusor pressure at maximum flow of more than 20 cmH₂O (Figure 54.5), has been considered to be suggestive of obstruction and used to construct female nomograms (Blaivas and Groutz 2000). The practical value of these observations remains unclear, as the clinical and radiological criteria used to define obstruction are arbitrary. Symptoms are often non-specific, and anatomical evidence of obstruction is often missing using videourodynamics or cystourethroscopy (Groutz et al 2000).

In contrast, other authors do not rely heavily on strict urodynamic criteria for the diagnosis of obstruction, and suggest that relative obstruction can exist in the presence

of normal or low detrusor pressures (Foster and McGuire 1993, Carr and Webster 1997). Obstruction after incontinence surgery is therefore diagnosed purely on the basis of a clear-cut temporal relationship between surgery and the onset of persistent voiding difficulty. Successful urethrolisis has even been performed on women who had acontractile bladders after stress incontinence surgery (Figure 54.6; Foster and McGuire 1993, Carr and Webster 1997), thus challenging the concept that obstruction only exists in the presence of high pressures.

Videourodynamics

More detailed studies on patients with prolonged postoperative voiding difficulty can be performed using videourodynamics. However, anatomical abnormalities (e.g. a narrowed or deviated urethra) leading to obstruction are only detected in a minority of patients (Groutz et al 2000).

Cystourethroscopy

This has been reported to reveal urethral strictures or fibrosis in approximately half of women who had suspected obstruction during pressure–flow studies (Groutz et al 2000).

Electromyography

Surface or needle electrodes can be used to evaluate distal urethral sphincter function. Failure of the sphincter to relax can be documented in cases of Fowler's syndrome (Fowler et al 1988). When used with urodynamics, simultaneous detrusor contraction and failure of relaxation of the sphincter can be observed in neuropathic patients (detrusor sphincter dyssynergia).

Figure 54.5 Voiding difficulty with obstruction due to urethral diverticulum (peak flow rate 10 ml/s, maximum detrusor pressure 80 cmH₂O, postvoid residual 600 ml).

Figure 54.6 Voiding difficulty with acontractile bladder after colposuspension (volume voided 7 ml, postvoid residual 350 ml).

Management

Short-term management

Voiding difficulty is usually managed with indwelling urethral catheters (e.g. Foley catheters). These are generally well tolerated but have been reported to be unpleasant by more than one-third of patients (Vierhout 1998). Catheters come in a variety of sizes and are made with a variety of materials (e.g. latex, silicone, polyvinyl chloride). Specialized catheters, impregnated with silver or antibiotics, have been developed to reduce the risk of infection, with evidence that they reduce the risk of bacteriuria by one-third to one-half in the short term (Schumm and Lam 2008). There is weak evidence that antibiotic prophylaxis reduces the rate of symptomatic UTI in patients using a urethral catheter in the short term (Niel-Weise and van den Broek 2005).

Suprapubic catheters may be preferred when surgery has greater potential for obstruction (e.g. colposuspension) or when patients undergoing surgery are already known to have voiding difficulty. They are more practical and allow patients to attempt voiding without needing recatheterization. The residual urine volume can be measured easily. Compared with urethral catheters, they have a lower incidence of sig-

nificant bacteriuria, voiding occurs earlier and patient acceptability is higher.

Early clean intermittent self-catheterization (CISC) has advantages compared with suprapubic bladder drainage in terms of hospital stay and sepsis. When considering potentially obstructive stress incontinence surgery, particularly in patients at high risk of voiding difficulty (see below), CISC should be discussed and taught beforehand as it is easier for patients to learn before rather than after surgery.

Long-term management

Indwelling urethral catheters are often used for chronic voiding difficulty, particularly in long-term care settings. While a variety of different catheters exist, insufficient evidence exists to recommend one over another (Jahn et al 2007).

Suprapubic catheterization is a better option than urethral catheterization. Epithelium will form in the tract in 6–8 weeks. A size 14F catheter should be used to keep the tract open and changed every 8–12 weeks. Vitamin C can acidify urine and prevent crust formation. There is usually no need for prophylactic antibiotics.

Indwelling catheters (urethral or suprapubic) are not ideal in the long term as they are conspicuous and demoralizing.

Urethral catheters interfere with coitus and ambulation, and can be associated with incontinence due to bypass. They are associated with recurrent UTI, stones, strictures and urethral erosion, and need to be changed frequently or irrigated due to blockage.

Rather than indwelling catheters, the preferred treatment for chronic voiding difficulty is CISC. This is based on the principle that retention rather than catheterization is the cause of infection. The advantages over an indwelling catheter are lower incidence of UTI and improved mental status.

The frequency of catheterization depends on severity of the voiding difficulty and residual urine volume. Old age and disability are not necessarily an impediment, but motivation and manual dexterity are essential. Most patients performing CISC have bacteriuria not requiring antibiotics, and treatment is only required in those with symptoms. More frequent catheterization and an increased fluid intake may be helpful if symptomatic infections occur. At present, there is no evidence that the incidence of UTI in patients performing CISC is affected by variables such as the type of catheter (coated or uncoated) or the technique used (single/sterile or multiple use/clean) (Moore et al 2007).

CISC has been shown to be effective in the long term. Two-thirds of patients available for follow-up 10 years after commencing treatment were satisfied and still performing the procedure, with no evidence of renal impairment (Diokno et al 1983). Although long-term follow-up studies may suffer from selection bias — most available responders are treatment 'successes' — up to 80% of patients find CISC easy, with only a minority reporting severe pain (Kessler et al 2009).

General measures may also be helpful in individual patients. These include standing or leaning forwards during voiding, abdominal straining, double voiding, voiding at regular intervals and treating constipation.

Women who experience voiding difficulty after surgery or post partum should be reassured that voiding function often improves with time. A positive view of CISC should be given, with support from continence advisors.

Role of drug therapy

The effect of drugs for the treatment of voiding difficulty has been disappointing. α -Adrenoreceptor antagonists to relax the urethra (e.g. phenoxybenzamine hydrochloride, alfuzosin), detrusor-stimulating drugs such as cholinergic agents (e.g. bethanechol chloride), anticholinesterase (e.g. distigmine bromide) and prostaglandins have been used with inconsistent results. Due to their inconsistent effect and unproven value, drugs are not currently recommended for the prevention and treatment of voiding difficulty in women.

Oestrogen may be of benefit for women with genital atrophy causing obstruction and voiding difficulty.

Role of surgery

Urethral dilatation and urethrotomy may be effective in patients with voiding difficulty due to urethral narrowing, particularly after anti-incontinence procedures. However, the benefit seems to be short lived as scarring is likely to recur and may even result in worsening obstruction. In addition, stress incontinence has been reported to reappear

(Delaere et al 1983). When this method is deemed necessary (e.g. for a traumatic stricture), repeated catheterization (e.g. CISC) is advisable to maintain patency.

Suprapubic and vaginal 'take-down' procedures involving urethrolisis, with or without additional resuspension procedures, have been described after retropubic procedures (e.g. colposuspension) (Foster and McGuire 1993, Carr and Webster 1997). Symptoms of voiding difficulty in these patients are usually combined with urgency symptoms. Despite the lack of uniformity with regards to patient selection, definition of obstruction, surgical treatment and outcome measures, it would appear that urethrolisis is a possible alternative to CISC. It may be suitable for patients who are unwilling or unable to perform the technique. However, the reported success rate is variable and unpredictable, and there is a risk of recurrent stress incontinence.

When voiding difficulty occurs after midurethral sling procedures, release of the tape can be performed. Loosening the tape by applying downward traction is usually possible in the immediate postoperative period (2–3 weeks), producing immediate symptomatic relief in most cases. Later, if scarring does not allow tape descent, transection of the tape (laterally or in the midline) has been described (Rardin et al 2002, Laurikainen and Kiiholma 2006, Segal et al 2006). While voiding function has been reported to improve in most women after late tape revisions, coexistent overactive bladder symptoms often remain unchanged (Segal et al 2006, McCrery 2007). The reported risk of recurrent stress incontinence after tape revision ranges from 5% to 50% (Klutke et al 2001, Rardin et al 2002, Karram et al 2003). Urethral injury may occur due to the formation of dense scarring between tape and urethra (Klutke et al 2001, Laurikainen and Kiiholma 2006).

Role of nerve stimulation

Unobstructive voiding difficulty can respond to techniques of nerve stimulation. The sacral nerves can be stimulated indirectly (posterior tibial nerve stimulation) or directly (sacral nerve stimulation). The precise mode of action is not known, and it is also not clear why the same techniques can help patients with an overactive detrusor muscle as well as an underactive detrusor muscle.

Posterior tibial nerve stimulation involves the placement of needle electrodes above the medial malleolus to stimulate the posterior tibial nerve, which contains mixed fibres from L5–S3. Early reports show objective improvement in voiding function, with approximately 60% of patients willing to continue treatment (Vandoninck et al 2004). However, the technique is time consuming and requires repeat stimulation.

Sacral nerve stimulation is a promising technique that uses an implantable system (Interstim device) to stimulate the pelvic nerves (at S3 level). An initial test procedure is performed to assess response, positioning a temporary electrode with an external stimulator. If appropriate, a permanent lead is then inserted and connected to a pulse generator positioned in the upper buttocks or anterior abdominal wall. In addition to unobstructed voiding difficulty, indications for sacral nerve stimulation include faecal incontinence, bladder overactivity and interstitial cystitis. A recent review reports a response rate for voiding difficulty of 38–68%, with

good medium-term results in 58–76% of responders (Bosch 2006). Technical problems and adverse events are unfortunately common (e.g. pain at the stimulator site, new pain, pain at the lead site, lead migration, infection, transient electric shock, changes in bowel function), with a reoperation rate of approximately 50% (Bosch 2006). There are no reports of long-lasting neurological complications.

Other treatments

A suprapubic vibration device (Queen Square bladder stimulator) has been shown to improve voiding in some patients with neurogenic bladders (Dasgupta et al 1997). The device was only effective in patients with a postvoid residual of less than 400 ml, reducing the postvoid residual from a mean of 175 ml to a mean of 68 ml (Dasgupta et al 1997). However, there is no evidence of benefit in other types of voiding difficulty.

Urinary diversion can be considered in selected cases as a last resort (e.g. ileal conduit or Indiana pouch).

Prevention

The early diagnosis of voiding difficulty and avoidance of bladder overdistension is crucial in order to reduce the risk of prolonged bladder dysfunction. As acute retention can be insidious and occur in women who appear to be voiding, close attention to bladder function after surgery or after delivery is important. This relies on good nursing care, ward protocols on bladder function, and easy access to portable bladder ultrasound to check postvoid residuals. Equally, bowel function should be taken into account as constipation can have a negative effect on voiding function.

Regular bladder emptying during labour, the use of catheters in women at risk (e.g. after instrumental deliveries, epidural, perineal trauma, etc.) and careful monitoring of voiding function after delivery or after catheter removal are considered essential preventative measures to avoid overdistension.

Appropriate placement of patients on the operating table may help to prevent postoperative voiding difficulty associ-

ated with the exacerbation of lumbar intervertebral disc prolapse.

Although urodynamics are not considered essential prior to stress incontinence surgery in all women (National Institute for Health and Clinical Excellence 2006), pressure–flow studies may help to identify women with existing or borderline voiding difficulty. Preoperative urodynamic variables (e.g. straining during voiding, voiding with low or absent detrusor contraction, low peak flow rate) may be predictive of postoperative voiding difficulty (Figures 54.2, 54.3 and 54.7), although the reported evidence is inconsistent. If urodynamics are not performed routinely, screening of women prior to surgery in order to identify those with voiding difficulty is simple and non-invasive (e.g. using uroflowmetry and/or ultrasound to check postvoid residual urine volumes). Elderly women and patients undergoing multiple procedures at the same time (e.g. midurethral slings combined with POP surgery) may be at increased risk of postoperative voiding difficulty. Patients at risk should be managed by experienced clinicians. Careful counselling is important in all cases. In women with existing voiding difficulty, consideration should be given to teaching CISC.

During surgery for urinary incontinence, excessive elevation should be avoided during colposuspension. For women undergoing midurethral sling procedures, it has been suggested that the cough test, with the observation of a reduction in leakage after tensioning the tape, can reduce the risk of postoperative voiding difficulty (Ulmsten et al 1996). However, the evidence for this is inconclusive, and in practice, the cough test is often poorly reproducible and influenced by the type of anaesthetic used. Consideration should be given to use of the TOT procedure in women at risk, as this is shown to be less likely to cause voiding difficulty (Latthe et al 2007).

A potentially difficult group of patients are those with intrinsic sphincter deficiency, as shown by reduced urethral closure pressures using urethral pressure profilometry. The TOT procedure has been shown to have a lower success rate than the TVT procedure in these patients (Schierlitz et al 2008). This is because the TOT procedure is less obstructive, and successful treatment of stress incontinence in such

Figure 54.7 Voiding with low peak flow rate and low detrusor pressure (12 ml/s at 9 cmH₂O for 414 ml volume and no residual).

patients often entails urethral support with an additional element of obstruction and the placement of a tighter tape; minimal degrees of tension can be crucial to achieve success without causing voiding difficulty. These women should be managed by experienced surgeons. A cough test in these circumstances may be useful as a measure of tension. The use of adjustable tapes has been proposed in patients with intrinsic sphincter deficiency, as well as in those at risk of voiding difficulty, as the tension can be modified in the postoperative period (Araco et al 2008, Romero Maroto et al 2008).

When voiding difficulty arises after midurethral sling procedures, early revision (within 2–3 weeks) is likely to be appreciated by patients, and loosening of the tape is usually possible. Urethral injury is unlikely to occur at this stage as there is minimal scarring.

Box 54.2 shows the key points for prevention.

Box 54.2 Prevention: key points

- Key times for prevention: labour, post partum and after surgery
- Avoidance of bladder overdistension: prophylactic use of catheters, surveillance and early diagnosis of voiding difficulty
- Screening and identification of patients at risk prior to surgery using flow studies and postvoid scan
- Pressure–flow studies in selected cases, if not routinely available
- Avoidance of bladder neck overelevation at colposuspension
- TVT procedure when using midurethral slings
- TOT procedure in women at risk but with no evidence of urethral sphincter deficiency
- Possibly cough test or adjustable tapes in women with urethral sphincter deficiency
- If voiding difficulty occurs, early tape revision is easier and less traumatic than later intervention

KEY POINTS

1. Normal voiding in the female occurs by detrusor contraction and pelvic floor relaxation, with or without abdominal straining. A minority of women with stress incontinence void without a detrusor contraction, possibly due to low urethral resistance.
2. When strict diagnostic criteria are applied (postvoid residual urine volume >30 ml), up to 39% of women attending a urogynaecology clinic have been found to have voiding difficulty.
3. Symptoms of voiding difficulty are non-specific.
4. Screening and diagnosis of voiding difficulty are based on uroflowmetry and measurement of the postvoid residual urine volume. Repeat measures are required to make a diagnosis. Urodynamics are useful in individual cases, although obstruction in women may not always lead to a detrusor pressure rise.
5. Attention to bladder care at key times (labour, post partum, after surgery) is essential to avoid bladder overdistension and prolonged voiding difficulty.
6. Surgery for POP and stress incontinence are common causes of voiding difficulty. Counselling before surgery is essential. Management after surgery mainly relies on the use of catheters. When obstruction is suspected, early relief (e.g. loosening of a midurethral tape) usually leads to resolution.

Introduction

Pelvic organ (urogenital) prolapse (POP) is a disorder unique to women and describes the herniation of one of the pelvic organs (uterus, vaginal apex, bladder, rectum) from its normal anatomical position into or beyond the vagina. Although women with asymptomatic POP can often be managed expectantly, current treatment options for symptomatic women are limited to vaginal pessaries and surgery. Surgical repair of POP is a rapidly evolving field, and the optimal reconstructive procedure for prolapse is one of the most debated issues in contemporary gynaecological practice.

Prevalence

Pelvic organ prolapse is very common. In the Women's Health Initiative (WHI), 41% of 27,342 women aged 50–79 years showed some degree of POP (Hendrix et al 2002, Figure 55.1). Indeed, with both life expectancy and rates of obesity increasing, the prevalence of POP is likely to rise. However, the majority of such women are symptom free and much of this prolapse is not considered clinically significant. Large cross-sectional studies have demonstrated rates of symptomatic POP of 3–11% (Tegerstedt et al 2005, Nygaard et al 2008, Fritel et al 2009). Women whose prolapse extends beyond the hymenal remnants are more likely to be symptomatic (Swift et al 2003). Although POP is rarely life threatening, it has a substantial impact on quality of life, such that 6.7% of women in the USA will undergo a surgical procedure for prolapse by 80 years of age (Olsen et al 1997).

Aetiology

The aetiology of POP is poorly understood, which is remarkable given the magnitude of the problem. Although multifactorial in nature, vaginal birth has emerged as the principal risk factor (Mant et al 1997). Avulsion injury to the levator ani during childbirth and, less commonly, pudendal neuropathy and fascial damage appear to be the most common causes (Dietz 2008a, Figure 55.2). Unsurprisingly, therefore, increasing parity, fetal macrosomia and perineal trauma increase the odds of subsequent POP, although the much-quoted link to instrumental vaginal delivery is not borne out in all studies (Uma et al 2005, Tegerstedt et al 2006).

Nulliparous women may also develop prolapse, and various non-obstetric aetiological factors have been identified (Miedel et al 2009). A number of reports, including the WHI, have demonstrated increasing rates of POP with advancing age (Hendrix et al 2002, Handa et al 2004), although a simple linear relationship is not universally accepted (Dietz 2008b). Some studies have shown an impact of ethnicity on POP, with lower rates of POP among Black women and higher rates among Hispanic women compared with White women (Hendrix et al 2002, Rortveit et al 2007). An association with body mass index (BMI) is generally agreed (Whitcomb et al 2009), and is of particular concern given the global rise in obesity. In addition, twin studies have demonstrated a clear genetic component to the disorder (Altman et al 2008), supported by stronger family histories among affected women (McLennan et al 2008).

The evidence directly linking hysterectomy and POP is not compelling and is potentially confounded by the

indication for the original hysterectomy. Among 384 women undergoing surgery for POP/incontinence, 60% had a previous hysterectomy and/or pelvic floor repair, suggesting a potential aetiological role (Olsen et al 1997). Despite this, the cumulative probability of requiring a POP repair 20 years following hysterectomy for non-prolapse is only 0–2%, raising the possibility that it is the history of prolapse and not the hysterectomy *per se* which is the dominant risk factor (Blandon et al 2007). Finally, conditions associated with increased intra-abdominal pressure (constipation, cough, heavy lifting) are generally considered to be risk factors for prolapse (Rortveit et al 2007).

Classification

Management of POP is determined primarily by the findings on physical examination; thus, a standardized and reproducible classification system is crucial. Initially, POP is classified by vaginal compartment into (Figure 55.3):

- anterior compartment prolapse (cystocele, urethrocele);
- posterior compartment prolapse (rectocele, enterocele); or
- apical prolapse (prolapse of uterus/vaginal vault).

The anterior compartment is the most common site of POP, although in most cases, there will be evidence of prolapse in more than a single compartment (Hendrix et al 2002). In addition to classifying POP by anatomical compartment, an assessment of prolapse severity (stage) is undertaken. A variety of systems to stage POP have been described (Figure 55.4). However, in 1996, the Pelvic Organ Prolapse Quantification (POP-Q) system was developed by consensus of international expert groups (Bump et al 1996). It is a more objective, site-specific system for staging pelvic support with proven inter- and intraobserver reliability (Hall et al 1996). The POP-Q system references nine vaginal points (two anterior, two posterior, two superior, two frontal and total vaginal length) to the plane of the hymen during Valsalva strain to create a 'topographic' map of the vagina (Figure 55.5). These anatomical points are measured follow-

Figure 55.3 Photographs in lithotomy position and sagittal magnetic resonance image showing vaginal wall prolapse. Prolapse might include (top to bottom): bladder (cystocele), small bowel (enterocele) or rectum (rectocele). Colour codes include purple (bladder), orange (vagina), brown (colon and rectum) and green (peritoneum).
Jelovsek JE, Maher C, Barber MD (2007) Pelvic organ prolapse. Lancet 369:1027–38.

ing demonstration of the maximum extent of the prolapse to determine the stage. Typically, the nine-point findings are translated into an ordinal staging system (stage 0–IV) to aid comparative analyses and facilitate more practical communication (Figure 55.4).

Pelvic Anatomy

Support of the pelvic organs is achieved through a complex interplay between the pelvic ligaments, muscles and endopelvic fascia which attach the pelvic organs to the bony pelvis to form a continuous support structure. The levator ani muscle group is the major structural component of the pelvic floor, and in practical terms, the pelvic floor is synonymous with the levator ani. Laterally, the levator is composed of iliococcygeus, a thin muscle layer originating from the arcus tendineus levator ani, a fascial condensation overlying the obturator internus muscle. The medial portion of the levator ani (pubococcygeus and puborectalis) arises from the pubic bone (lateral to the pubic symphysis) and forms a sling around the bladder, urethra, vagina and rectum. The obturator internus and piriformis muscles form the pelvic sidewall. The obturator internus is a large fan-shaped muscle which can be palpated vaginally. Another prominent connective tissue structure, the arcus tendineus fascia pelvis ('white line'), passes from the pubic tubercle to the ischial spine and provides lateral pelvic support to the anterior vaginal wall (analogous to the cable of a suspension bridge). The urethra and vagina pass through the urogenital

hiatus in the levator ani, and it is through this opening that POP occurs. The levator ani muscles, together with coccygeus and the overlying superior and inferior fascia, form the pelvic diaphragm.

On each side of the pelvis, a dense layer of connective tissue, the endopelvic fascia, envelops the uterus and cervix and attaches to the pelvic sidewall. As well as providing support, the endopelvic fascia also serves as a neurovascular conduit and is composed of collagen, smooth muscle, blood vessels and nerves. In certain areas, thickened condensations of this fascia form pelvic 'ligaments' which add support. The clinically important ligaments include the uterosacral ligaments (extending laterally from the posterior cervix to the anterior sacrum), the cardinal ligaments (transverse cervical/Mackenrodt's ligaments, extending from the lateral cervix and upper vagina to the pelvic sidewall) and the round ligament (extending from the uterine cornu to the labia majora as the superior part of the broad ligament) (Raizada and Mittal 2008).

DeLancey introduced the concept of three levels of connective tissue support in the anterior pelvis. Level I (apical vaginal) support is via the uterosacral/cardinal ligament complex, and damage at this level results in uterine/vaginal vault prolapse (DeLancey 1992). Level II (midvaginal) support is achieved via the endopelvic fascia and its lateral insertion into the white line. Level III (distal vaginal) support incorporates the endopelvic fascia anteriorly and the perineal body posteriorly. Anterior and posterior compartment prolapse result from damage to level II/III support, respectively. Although DeLancey's system creates artificial divides

in what is essentially a continuous connective tissue structure, it does aid understanding of how loss of support correlates with clinical findings, and is widely reproduced in the gynaecological literature.

Clinical Presentation

Patients who seek medical care have a wide range of symptoms (Table 55.1). Women frequently present with a sensation of 'something coming down' or of 'something falling out of the vagina'. Other women may see or feel a vaginal bulge or they may complain of less specific herniation symptoms, such as pelvic pressure or heaviness. As might be expected, a visible vaginal bulge correlates better with objective evidence of POP on examination than the more general complaint of pelvic heaviness or discomfort (Miedel et al 2008).

Urinary symptoms

Among 237 women with symptomatic POP, 87% reported frequency/urgency, 73% reported urinary incontinence and 50–60% reported symptoms of voiding dysfunction (Ellerkmann et al 2001). A complex relationship exists

Table 55.1 Common symptoms associated with pelvic organ prolapse

Vaginal symptoms
Sensation of pressure ('something coming down')
Seeing or feeling a bulge
Dyspareunia
Urinary symptoms
Urinary incontinence
Frequency

Hesitancy
Poor stream
Digitation/positional change needed to void
Bowel symptoms
Incontinence of flatus/faeces
Straining to defaecate
Sensation of incomplete emptying
Faecal urgency
Vaginal/anal digitation to defaecate
Splinting perineum to defaecate

between POP and stress urinary incontinence, and may result from shared risk factors rather than a direct causal link (Smith and Appell 2005). In practice, many women present with both cystocele and stress incontinence, and loss of the anterior vaginal wall support is thought to contribute to urethral hypermobility and subsequent stress incontinence (DeLancey 2002). However, the relationship is not linear and some studies have demonstrated lower rates of stress leakage in more advanced POP (Yalcin et al 2001, Burrows et al 2004). This is likely due to a direct compressive effect or a urethral kinking mechanism, and is important given the risk of hidden or 'occult' stress incontinence manifesting once the prolapse is reduced (see 'Investigation' section). Interestingly, posterior vaginal wall prolapse has recently been linked to stress incontinence (Miedel et al 2008). More advanced POP can produce obstructive voiding symptoms or, rarely, urinary retention. The need to manually reduce a bulge to void is progressively linked to more severe POP (Burrows et al 2004, Miedel et al 2008). The relationship between POP and overactive bladder symptoms has not been studied as extensively. Analysis of 330 women undergoing surgery for POP or incontinence found that urgency/urge incontinence occurred more often in women with less advanced prolapse (Burrows et al 2004). Other studies, however, have shown a positive association between urge incontinence and both anterior and posterior compartment prolapse (Miedel et al 2008). This is supported by short-term improvements in overactive bladder symptoms following prolapse repair (Nguyen and Bhatia 2001, Digesu et al 2007).

Bowel symptoms

Bowel symptoms and difficulty with defaecation are common symptoms among women with POP. These include straining, sensation of incomplete emptying and the need to manually assist defaecation (digital pressure to the vagina or

perineum). Among 280 women with symptomatic POP, almost three-quarters (73%) reported at least one bowel symptom (Miedel et al 2008). The most consistently reported prevalence of faecal incontinence associated with POP ranges from 14% to 19% (Jackson et al 1997, Burrows et al 2004, Jelovsek et al 2005, Miedel et al 2008). The extent of POP does not appear to predict bowel symptoms (Jelovsek et al 2005), although the need to manually assist defaecation has been associated with more severe prolapse (Burrows et al 2004). Much has been written about the relationship between posterior compartment prolapse and constipation, and it has been suggested that constipation contributes to the development of rectocele and vice versa. However, the exact nature of the association remains uncertain. It is notable that several studies have failed to identify a relationship between constipation and POP (Samuelsson et al 1999, Jelovsek et al 2005).

Sexual dysfunction

Sexual dysfunction is very common in women attending urogynaecology clinics (Pauls et al 2006), although it may not be volunteered due to patient embarrassment or poor history taking. Sexual satisfaction is a complex issue and studies examining the association between POP and sexual dysfunction have yielded conflicting results. Although high rates of satisfaction have been reported in women with POP (Barber et al 2002, Burrows et al 2004), other data have shown POP to have an adverse effect on sexual function (Rogers et al 2001, Novi et al 2005). It appears that women with POP are more likely to complain of problems with sexual function than those with urinary incontinence (Barber et al 2002). Weber found no differences in measures of sexual function in women with POP and incontinence compared with continent women without prolapse (Weber et al 1995). Furthermore, the benefits of pelvic floor surgical repair on sexual function have not been consistent (Thakar 2009).

Prediction of symptoms

Attempts have been made to correlate the severity (stage) of POP with the likely development of symptoms. Consistently strong correlations between increasing severity of POP and the development of symptoms have not been demonstrated (Burrows et al 2004). Many studies indicate a lower rate of stress incontinence in more severe anterior compartment prolapse. Miedel et al (2008) showed that most urinary and bowel symptoms associated with POP lack stage dependency, although there was correlation between a vaginal bulge and more advanced prolapse in all compartments. However, a large prospective study of 477 patients suggested that women whose prolapse extends beyond the hymenal remnants are more likely to be symptomatic (Swift et al 2003).

Physical examination

All women who present with symptoms consistent with POP should undergo a physical examination, including pelvic examination. Although some authorities advocate the need for physical examination in the standing position for

all patients, use of the dorsal lithotomy position with Valsalva has been shown to be as good (Swift and Herring 1998). In practice, many clinicians examine women lying supine during resting and straining, and it is reasonable to reserve the standing position for women who feel that their prolapse is not being seen at its worst extent in that position (American College of Obstetricians and Gynecologists 2007). Conventionally, prolapse is examined while asking the woman to perform a Valsalva or cough stress test so that the maximum extent of the prolapse can be appreciated. A Sim's speculum (or the posterior blade of a bivalve speculum) is inserted into the vagina to retract the posterior wall and allow visualization of the anterior wall; the extent of any prolapse is noted while the woman strains. The process is repeated for the posterior wall with the speculum retracting anteriorly. Sometimes, an anterior wall prolapse may be better appreciated with the woman in the left lateral position and her right hip flexed. Finally, the cervix or vaginal vault is assessed either through visualization or with gentle traction from a ring forceps, although, in practice, many women find the latter uncomfortable. Areas of bleeding/ulceration, which can be seen in prolapse extending past the introitus in particular, should be noted (Figure 55.6). Women with recurrent prolapse should have a meticulous examination to assess previous surgical repair and plan future management. Staging of the prolapse should be recorded for all compartments using the practitioner's chosen method, although the POP-Q system is the inter-

nationally accepted standard (Figure 55.5, see 'Classification' section).

In addition to staging POP, a number of other features of the physical examination are noteworthy. Abdominal palpation and a bimanual pelvic examination should be performed in these patients as, occasionally, a large pelvic mass, such as a fibroid uterus or ovarian mass, may be detected. Although routine rectal examination for all patients is unnecessary, it can be useful in defining a posterior compartment prolapse, particularly where there is suspicion of an enterocele (which can be felt between a thumb placed in the vagina and a finger placed in the rectum). In addition, it can be useful to look for stress urinary incontinence on provocation by asking the patient to cough, assuming the bladder has not been emptied recently. Furthermore, in cases of advanced anterior compartment prolapse in women who do not complain of urinary leakage, there is concern that prolapse reduction may unmask 'occult' stress incontinence. Therefore, a cough test following temporary reduction of the prolapse into a more anatomical position (manually or with a cotton swab or ring forceps) may be useful (Fatton 2009). In a large randomized trial, reduction using a cotton swab most closely reproduced postoperative status following sacrocolpopexy compared with other reduction techniques (Visco et al 2008). Finally, digital assessment of the strength of the patient's pelvic floor muscle contraction is beneficial in women with concomitant stress urinary incontinence.

Investigation

A thorough physical examination is the cornerstone of POP management, and further investigations are usually second line. In women with urinary symptoms, a midstream specimen of urine should be cultured to exclude infection. Additionally, where there is suspicion of a voiding problem, women should undergo a voiding study with measurement of the residual volume using an ultrasound scan. If one is not available, the postvoid residual volume can be assessed using an in-out catheter.

The most contentious issue in the investigation of POP is the need for preoperative urodynamic testing. Women with POP without stress leakage have a 10–50% chance of developing de-novo ('occult') stress incontinence post repair (Fatton 2009). An anti-incontinence procedure may be performed concomitantly but will likely overtreat a proportion of women, and increases postoperative voiding problems and overactive bladder symptoms (de Tayrac et al 2004). Alternatively, a two-stage strategy can be adopted, where an interval continence procedure is reserved for patients with troubling stress urinary incontinence following prolapse repair. The use of preoperative urodynamics to better stratify patients into those who may or may not benefit from concomitant continence surgery has been suggested. However, there is little evidence that preoperative urodynamics improves the outcome of prolapse surgery (Roovers and Oelke 2007). The CARE (Colpopexy and Urinary Reduction Efforts) trial did show that women with POP and preoperative urodynamic stress incontinence during reduction testing had a higher rate of stress leak following abdominal sacrocolpopexy without the conti-

nence procedure. It is notable that even with optimal prolapse reduction during preoperative urodynamics (by cotton swab), one-third of women who were dry before surgery developed postoperative stress incontinence (Visco et al 2008).

Various radiographic modalities have been proposed to further define the extent of POP, although none are in mainstream clinical use. Dynamic magnetic resonance imaging (MRI) is the most commonly described technique (Law and Fielding 2008, Taylor 2009). Dynamic MRI offers excellent anatomical detail and allows visualization of all three compartments together (Figure 55.7), but is expensive and dispute remains over the appropriate radiological landmarks for staging POP (Broekhuis et al 2009). Transperineal ultrasound (TPUS), and increasingly three- and four-dimensional TPUS, have also been used in staging POP radiologically (Dietz 2004). Recently, moderate-to-good correlation was demonstrated between three-dimensional TPUS and defaecography (traditionally the gold standard investigation) in the assessment of posterior compartment prolapse (Steensma et al 2009). However, TPUS does not appear to be superior to clinical assessment of POP (Kluivers et al 2008). Finally, anorectal physiology studies (including anal manometry and pudendal nerve latency) and endoanal ultrasound should be considered in women with symptoms of bowel dysfunction, particularly faecal incontinence.

Preventative Strategies/Natural History

POP and surgical prolapse repair place a significant demand on healthcare resources. Therefore, strategies to minimize POP and reduce the resultant disease burden are vital (Subramanian et al 2009).

Lifestyle modification

Four-year prospective results from one of the WHI study centres have confirmed that progression of POP over time is not inevitable; in some cases, POP can regress. Specifically, among 259 non-hysterectomized postmenopausal women undergoing serial POP-Q assessments, the maximum vaginal descent increased by ≥ 2 cm in 11% and regressed by this amount in 2.7% (Bradley et al 2007). POP progression was more likely in obese women, of higher parity (particularly for five children or more) and with more severe baseline degrees of prolapse. Progression was less likely in smokers, although this may be related to a lower BMI in women who smoked rather than a genuine protective effect. Another large secondary analysis from the WHI study confirmed a higher rate of progression in women with raised BMI, but found that weight loss was not associated with regression of POP, suggesting irreversible pelvic floor changes secondary to obesity (Kudish 2009). Therefore, although weight loss forms part of the standard advice given to overweight women with POP, highlighting the importance of avoiding weight gain in women of normal BMI may be more valuable. Pelvic floor muscle (Kegel) exercises are frequently recommended for women with POP. Although they are an effective therapy in stress urinary incontinence (which may coexist), pelvic floor exercises are of no proven benefit in the prevention of POP, although studies are lacking (Bø 2006).

Obstetric risk

Given the clear aetiological link between vaginal childbirth and POP, the role of caesarean delivery as a strategy to prevent POP is debated (Richter 2006, Weber 2007). The relative contributions made by the pregnancy, labour and mode of delivery itself are difficult to tease out. Based on POP-Q assessments on 94 primigravidae at 36 weeks of gestation and again at 6 weeks post partum, intrapartum caesarean section performed during the first stage of labour has not been shown to protect against POP compared with women undergoing vaginal delivery (Sze et al 2002). A similar study of 135 primigravidae involved POP-Q assessments on women from each trimester and post partum (O'Boyle et al 2005). POP was significantly more common in both the third trimester and post partum compared with the first trimester. Forty percent of women examined in the third trimester had stage II POP or worse. Among postpartum women, there was a higher incidence of stage II POP in the vaginal birth group compared with those who delivered by intrapartum caesarean. Although this finding contrasts with that of Sze et al (2002), the role of elective caesarean delivery was not examined and both studies were underpowered to determine the impact of mode of delivery on POP. A survey of 4458 women showed POP to be three times more common among vaginally

parous women compared with nulliparous women [adjusted odds ratio (AOR) 3.2]. A history of caesarean delivery alone was protective (AOR 1.6 compared with nulliparous). However, elective prelabour caesarean conferred a higher benefit than caesarean in labour, suggesting that intrapartum events and not simply mode of delivery contribute to POP (Lukacz et al 2006).

Hysterectomy

The precise incidence of posthysterectomy POP is difficult to determine. A recent case-control study demonstrated a cumulative incidence of vaginal vault prolapse repair of 0.5% at 3–23 year follow-up (Dällenbach et al 2008). Overall, rates of pelvic floor repair are higher in women whose original hysterectomy was performed for prolapse compared with other clinical indications (Mant et al 1997, Blandon et al 2007). Numerous surgical strategies to prevent posthysterectomy vault prolapse have been described. The McCall and modified McCall culdoplasty techniques involve various means of anchoring the uterosacral pedicles to the vaginal vault during vaginal hysterectomy. Many studies have reported success rates in excess of 90% in preventing enterocele/vault prolapse at 12–108 months (Chene et al 2008). These techniques are superior to the Moschowitz procedure in this regard (Cruikshank and Kovac 1999). Some authorities recommend prophylactic sacrospinous ligament suspension at the time of vaginal hysterectomy if the vault descends to the introitus during closure (Royal College of Obstetricians and Gynaecologists 2007), but there is no evidence to support this practice.

Treatment

Many women with POP, particularly those with minor degrees of prolapse not extending past the hymenal remnants, complain of little or no discomfort. Adopting a policy of expectant management is entirely appropriate in such cases. Indeed, these women are often relieved to be told that surgery is not always warranted for POP. However, more proactive treatment may be necessary if problems, such as urinary obstruction, chronic vaginal ulceration or worsening POP symptoms, arise.

Non-surgical treatment

Pelvic floor muscle training

As has been noted above, the effectiveness of pelvic floor exercises in the treatment of POP remains unproven. Although pelvic floor muscle training is unlikely to cause harm and may benefit stress urinary incontinence, there are associated cost implications. An international, multi-centre, randomized controlled trial to assess the role of physiotherapy in prolapse is currently recruiting (<http://www.chartrials.abdn.ac.uk/poppy/index.php>). A pilot study of 47 women with stage I or II POP showed improvement in both subjective and objective measures of POP in women treated with pelvic floor muscle training and lifestyle advice compared with lifestyle advice alone (Hagen et al 2009).

Weight loss

A large population-based study of almost 5500 Swedish women showed that women who are overweight (BMI 26–30) are twice as likely to complain of symptomatic POP as women of normal weight (BMI 20–24, Miedel et al 2009). Weight loss should be encouraged in the management of POP for all women as it does not cause harm, reduces peri-operative complication rates if surgery is later contemplated, and is of proven benefit in treating stress urinary incontinence, which often coexists (Subak et al 2009).

Vaginal pessaries

Vaginal pessaries represent the only proven non-surgical option for women who require treatment for POP. Although all women can be offered a trial of pessary use, they are particularly useful for women who decline surgery or are medically unsuitable for surgery, during pregnancy, and as an interim measure prior to surgery or for those who desire future childbearing. Pessary materials have evolved and are now made predominantly from non-reactive silicone, which is non-allergenic, durable and autoclavable (Shah et al 2006). A wide range of styles and shapes is available, and the ring pessary, which permits sexual intercourse, is the most widely used (Cundiff et al 2000, Figure 55.8). Some styles are also useful in the treatment of urinary incontinence. Pessaries are valid treatment options for advanced POP, although sturdier, 'space-filling' designs, such as the Gelhorn pessary, may be required (Powers et al 2006). In advanced POP, double pessaries are occasionally used (Singh and Reid 2001).

Fitting a pessary is based on a clinical assessment of vaginal length, introital size and severity of POP, and is often a process of trial and error. A pessary which is too small will not be retained, whereas one that is too large will be uncomfortable. The aim should be to place the largest size of which the patient is unaware. Most women will require trials of more than one option (Hanson et al 2006), and it is good practice to schedule a return appointment to the clinic 1–2

Figure 55.8 Different types of vaginal support pessaries.

Elneil S (2009) Complex pelvic floor failure and associated problems. *Best Practice & Research Clinical Gastroenterology* 23: 555–573.

weeks following the initial fitting to assess discomfort and the development of vaginal bleeding or de-novo incontinence. Results from multiple studies suggest that pessaries can be successfully fitted in approximately two-thirds of candidates. Reported predictors of an unsuccessful fitting include prior prolapse surgery or hysterectomy, younger age, higher parity and obesity (Mutone et al 2005, Nguyen and Jones 2005). Local oestrogen cream improves the success rate, even for patients taking systemic hormone replacement, and should be offered to all women (Hanson et al 2006). Women in whom pessaries are successfully fitted usually require assessment, vaginal examination and pessary removal/cleaning/reinsertion every 4–6 months, although there is no clear consensus on the most appropriate follow-up protocol. For those who can be taught self-removal, less frequent visits are reasonable. Prolonged use can lead to vaginal erosion with subsequent granulation formation. This can cause vaginal discharge and bleeding, which are common reasons for discontinuation. However, serious complications such as fistula, and urinary and bowel obstruction are rare and are usually limited to pessaries that have been neglected (Arias et al 2008).

Surgery

Women with symptomatic POP who decline or fail pessary management require surgical intervention. The surgical procedures and approaches available to women are rapidly evolving, due primarily to concerns about the longevity of more traditional prolapse repairs. The aims of surgical intervention are to restore anatomy, relieve symptoms, and preserve or restore urinary, bowel and sexual function. Among US women undergoing prolapse surgery, 20% will have a concomitant anti-incontinence procedure (Brown et al 2002).

In patients considering surgical management of POP, a fastidious preoperative work up is essential as a number of these patients have significant comorbidities. During surgery, the use of Allen legs in the vaginal and laparoscopic procedures will reduce iatrogenic injury to the patient and allow safer manipulation of the legs. The use of self-retaining retractors, such as the ReeTrakt (Insightra Medical, Irvine, CA, USA), will aid vaginal surgery significantly (Figure 55.9).

Figure 55.9 ReeTrakt (Insightra Medical, Irvine, CA, USA).

Following surgery, attention should be paid to thromboprophylaxis and prophylactic antibiotic coverage. Appropriate dietary advice, fluid intake and, if necessary, stool softeners should be given to avoid the woman straining at stool in the immediate postoperative period.

Options for surgical repair of POP can be classified by compartment and further subdivided into vaginal and abdominal approaches. However, it is important to remember that prolapse of a single compartment is rare, and failure to repair all defects may result in higher recurrence rates. Level I evidence supports a superior restoration of anatomy via the abdominal route, which may be offset partly by higher short-term morbidity associated with a more invasive approach (Maher et al 2007, Brubaker et al 2009). Comparison of different surgical techniques for POP is made difficult by the lack of consensus on outcome measures, which include subjective cure by symptoms, anatomical cure by examination and/or the need for reoperation for recurrent POP.

Surgery for apical prolapse

The apex is the cornerstone of good pelvic organ support, and if the uterus or vaginal vault is poorly supported, the posterior and, in particular, the anterior vaginal wall are exposed to intra-abdominal forces (Lowder et al 2008). Optimal surgical repair of advanced anterior compartment prolapse will often necessitate an apical support procedure (Rooney et al 2006). Abdominal sacrocolpopexy and vaginal sacrospinous ligament suspension are the two most common procedures performed for apical prolapse. Abdominal sacrocolpopexy involves suspending the vaginal apex to the anterior longitudinal ligament of the sacrum using an intervening material, typically a synthetic mesh. Traditionally, this is performed via a Pfannenstiel incision, and reported anatomical success rates range from 74% to 100% (Hilger et al 2003, Nygaard et al 2004). Laparoscopic sacrocolpopexy aims to minimize the morbidity while retaining the benefits associated with abdominal sacrocolpopexy (Figure 55.10).

Figure 55.10 Mesh applied to the perineal body and on to part of the vaginal vault during a laparoscopic sacrocolpopexy procedure.

Elneil S (2009) Complex pelvic floor failure and associated problems. *Best Practice & Research Clinical Gastroenterology* 23: 555–573.

Although no randomized trials comparing these two approaches with sacrocolpopexy have been published, medium-term observational data from more than 1000 patients have shown a 94% satisfaction rate and 6% need for reoperation (Ganatra et al 2009).

Sacrospinous ligament suspension (sacrospinous colpopexy) suspends the vaginal apex to the lateral aspect of the sacrospinous ligament using permanent suture material. Typically, the sacrospinous ligament suspension uses an extraperitoneal approach to the right sacrospinous ligament, although bilateral fixation may be performed. Reported anatomical cure rates following sacrospinous fixation range from 63% to 97% (Sze and Karram 1997, Maher et al 2004). Meta-analysis comparing abdominal sacrocolpopexy with sacrospinous ligament suspension found lower rates of recurrent vault prolapse [relative risk (RR) 0.23] and dyspareunia (RR 0.39), but a longer operating time (on average 21 min), increased cost and increased risk of mesh erosion in women undergoing abdominal sacrocolpopexy (Maher et al 2007). Mesh erosion complicates 2–11% of sacrocolpopexies (Nygaard et al 2004), with higher rates among smokers and, in some studies, women undergoing concomitant hysterectomy (Cundiff et al 2008). It may be reasonable to offer younger women the higher success rate with sacrocolpopexy; in older, frailer patients, the reduced morbidity and quicker return to daily activities associated with sacrospinous ligament suspension may be more appropriate. In addition to abdominal sacrocolpopexy and sacrospinous ligament suspension, a number of other procedures for apical prolapse have been described. Iliococcygeus suspension involves suspension of the vaginal vault to the iliococcygeus fascia over the levator plate. Theoretically, this is meant to reduce anterior wall recurrence and pudendal neurovascular injury compared with sacrospinous ligament suspension, although data are sparse and limited to case series (Meeks et al 1994, Maher et al 2001). Uterosacral ligament suspension is also performed vaginally and, although originally described 80 years ago (Miller 1927), attention has once again started to focus on the uterosacral ligament as a potential site for apical suspension (Shull et al 2000, Silva et al 2006), although ureteric injury remains a concern and randomized trials are needed.

Surgery for anterior compartment prolapse

The traditional procedure for anterior compartment prolapse has been the anterior colporrhaphy (Kelly 1913). Many variations have been described, involving midline plication of the vaginal muscularis and adventitia followed by excision and/or plication of redundant vaginal wall mucosa. Case series have reported success rates of 80–100% for anterior colporrhaphy; however, prospective randomized trials have shown the success of anterior colporrhaphy alone to be only 37–57% (Sand et al 2001, Weber et al 2001). It is likely that such variable rates of success result from the heterogeneous nature of anterior compartment prolapse and different surgical techniques. In addition to midline defects of the endopelvic fascia, lateral or paravaginal defects resulting from detachment of the lateral vaginal wall from the arcus tendineus fascia pelvis ('white line') can also give rise to anterior support abnormalities. This concept of 'site-specific' anterior vaginal wall defects was introduced by George White 100 years ago (White 1909), and subsequently

repopularized by Cullen Richardson in the 1970s (Richardson et al 1976). Originally, this procedure was described as a treatment for stress urinary incontinence, but significant benefits for anterior wall support were demonstrated. Paravaginal repair can be approached both transabdominally and transvaginally, which largely depends on surgeon preference as no direct comparison has been performed. The procedure involves reapproximating the white line with the thickened lateral portion of the fascia overlying the obturator internus muscle. Similar success rates have been reported from both abdominal paravaginal repair (76–97%) and vaginal paravaginal repair (67–100%), although the transvaginal approach is technically more difficult (Brubaker et al 2009). Currently published data on laparoscopic paravaginal repair are sparse; of the studies reported, many include a concomitant Burch colposuspension (Diwadkar et al 2008). In one prospective study, the objective cure rate of laparoscopic paravaginal repair at 14 months was 74% (Behnia-Willison et al 2007).

Given the relatively high failure rate for anterior colporrhaphy and following on from the successful use of grafts in abdominal hernia repair and tension-free vaginal tape, there has been a recent trend towards the use of graft materials in prolapse surgery to augment more traditional repairs (Sung et al 2008, Jakus et al 2008). However, the overall advantage of mesh and other graft materials has not been definitively proven, as the potential benefit in reducing failure rates must be balanced against the risk of mesh-related complications. Indeed, the appropriate use of reconstructive materials in prolapse surgery has become one of the most debated issues in contemporary gynaecological practice, with most authorities acknowledging the risk of adverse events and the lack of data on long-term functional outcomes (Murphy 2008, Brubaker et al 2009). Grafts may be biological (allograft, autograft or xenograft) or synthetic in nature. Synthetic materials are further subclassified as absorbable or non-absorbable and by pore size [macroporous (>75 µm) or microporous (<75 µm)]. A meta-analysis of ten randomized controlled trials found that at 1 year post-operatively, women who had anterior repair with graft use had a lower rate of recurrence than women undergoing standard 'native tissue' repair (odds ratios 0.56 and 0.44 for biological and absorbable synthetic mesh, respectively) (Foon et al 2008).

The risk of mesh-related complications — predominantly mesh erosion, infection, mesh shrinkage and fibrosis — remains a concern (Bako and Dhar 2009, Figure 55.11). Additionally, since 2004, trocar-guided transvaginal surgical mesh 'kits' have gained rapid widespread acceptance due to the suggestion that reconstructive materials in prolapse surgery require 'anchoring' outside of the affected tissues (Elmér et al 2009). A variety of armed mesh kits are currently available, including the Perigee/Apogee (American Medical Systems), the Prolift (Johnson & Johnson) and the Posterior Intravaginal Slingplasty (Tyco Healthcare).

However, randomized data to support the use of mesh kits are sparse. Furthermore, in addition to the risk of 'mesh-related' complications noted above, these kits also have the added risk of 'trocar-related' complications, including bladder/rectal perforation and vascular injury (Feiner et al 2009). A different procedure, using a trocarless mesh and a silicone vaginal device to support the graft during tissue ingrowth, has been described (Carey et al 2008, Figure 55.12).

Figure 55.12 Silicone vaginal support device.
Carey M et al. (2008) Vaginal surgery for pelvic organ prolapse using mesh and a vaginal support device. BJOG 115:391–7.

The same authors recently reported a modification of this technique, which uses a silicone device and inflatable balloon to support the mesh repair (Gynecare Prosima, Ethicon, Somerville, NJ, USA; Figure 55.13). A recent multi-centre study described an 88% success rate at 1 year for women with stage II and III prolapse following this procedure. The vaginal support device was shown to be well tolerated (Slack et al 2009).

Surgery for posterior compartment prolapse

The standard surgical procedure for posterior compartment prolapse is the posterior colporrhaphy, involving midline plication of the rectovaginal fascia. The traditional description of this procedure also involves midline plication of the levator ani muscles (Francis and Jeffcoate 1961), although

Figure 55.13 Gynecare Prosima, Ethicon, Somerville, NJ, USA.

this can result in high rates of postoperative dyspareunia among sexually active women. Analogous to the anterior compartment, site-specific repair of posterior defects has also been described (Richardson 1993), whereby rectovaginal defects are identified by a rectal finger. A prospective randomized trial found higher anatomical cures at 1 year in the colporrhaphy group (86%) compared with the site-specific repair group (78%) (Paraíso et al 2006). In addition, modification of the standard sacrocolpopexy to include extension of the posterior mesh to the rectovaginal septum or perineal body can also benefit posterior prolapse.

Although gynaecologists conventionally repair posterior compartment prolapse transvaginally in the lithotomy position, the colorectal surgeon typically performs a transanal repair. Level I evidence to support the superiority of the transvaginal repair over the transanal approach has been published (Nieminen et al 2004). There is currently no evidence to support the routine use of graft augmentation in the surgical repair of posterior compartment prolapse (Brubaker et al 2009).

Laparoscopic/robotic pelvic floor repair

A variety of laparoscopic reconstructive procedures have been described which aim to improve anatomical detail, minimize surgical morbidity and reduce hospital stay, while retaining the advantages of the abdominal operation. Paravaginal repair, sacrocolpopexy, enterocele repair and uterosacral ligament suspension have all been described laparoscopically (Paraíso et al 2006, Behnia-Willison et al 2007). However, in many cases, direct comparison with the gold standard has not been performed, and the efficacy of a standard surgical technique should not be compromised simply so that the procedure can be completed laparoscopically.

To date, robotic surgery has been most widely accepted in urological oncology. Recently, a limited number of publications have described the use of robotic systems in achieving

sacrocolpopexy, with 95% success at 24 months, albeit with small numbers (Elliott et al 2006, Akl et al 2009). Robotic-assisted laparoscopic hysterectomy has also been reported (Reynolds and Advincula 2006). It is unlikely, however, that robotics will significantly impact pelvic reconstructive surgery, at least in the short term.

Obliterative surgical procedures

In addition to the reconstructive surgical procedures outlined above, women who do not wish to preserve coital function may be suitable for a vaginal obliterative procedure. Colpocleisis is a relatively straightforward surgery associated with high cure rates and fast recovery times (Hullfish et al 2007). It may be performed in women with or without a uterus, and involves excision of rectangular pieces of vaginal epithelium anteriorly and posteriorly, vaginal inversion and closure with sutures, thus obliterating the vaginal space. Among appropriately selected women, studies have demon-

strated low rates of regret for loss of sexual function (Wheeler et al 2005). There is a risk of stress urinary incontinence developing after colpocleisis, and a concomitant midurethral tape may be appropriate in selected cases.

Conclusions

POP is a significant cause of morbidity among women. It presents a huge disease burden to society which, given the ageing population, is unlikely to abate. Although many women with POP are symptom free, the optimal management of women who desire treatment continues to generate considerable debate among gynaecologists. The appropriate use of graft materials to augment traditional surgical techniques and the role of laparoscopic pelvic floor repair are particular sources of controversy. Good quality, randomized studies to guide practitioners and answer these uncertainties are urgently needed.

KEY POINTS

1. Prolapse is a common condition with a long-term cure rate which may not exceed 70%.
2. Vaginal delivery is the most common cause.
3. Prolapse may affect all compartments and both urinary and anal sphincters, and therefore examination and investigation must include all of these.
4. Validated outcome measures, rather than terms such as 'slight' or 'moderate', should be used.
5. Preventive measures include avoidance of unnecessary lifting, straining at stool and a prolonged second stage of labour.
6. A variety of pessaries are available and should be used when appropriate.
7. Urinary incontinence may be masked by prolapse, and urodynamic studies are advised before prolapse surgery.
8. Surgery for recurrent prolapse may need mesh reinforcement.
9. Complex prolapse should only be attempted by those familiar with, and trained in, prolapse surgery.

AETIOLOGY	865	KEY POINTS	872

Introduction

'Cystitis' is a term used for irritative urinary symptoms of frequency, urgency, suprapubic pain and dysuria. These symptoms of altered lower urinary tract sensation may be of recent onset (acute), longstanding (chronic) or recurrent. They may be caused by a variety of intravesical pathology such as infection, calculi, drug-induced inflammation, non-infective inflammatory processes due to local [e.g. painful bladder syndrome (PBS)] or systemic conditions (e.g. sarcoidosis), benign or malignant lower urinary tract tumours, or extravesical pelvic pathology such as pelvic masses (e.g. fibroids, endometriosis). Accurate diagnosis, appropriate intervention and therapy requires careful patient evaluation and a sound understanding of the differential causes (Figure 56.1).

Women with longstanding or recurrent chronic symptoms are often treated as recurrent bacterial cystitis. Often, it is only after a poor response to antibiotics or failure to culture uropathogens that an alternative diagnosis is considered. It is essential that these women have a thorough evaluation to exclude any serious underlying pathology (e.g. carcinoma) so that effective treatment can be commenced. Women with chronic irritative symptoms frequently have conditions such as PBS (formerly known as 'interstitial cystitis') or urethral syndrome. The pathogenesis for these conditions is poorly understood, and response to current therapy is often unsatisfactory.

Definitions

The Standardisation Sub-committee of the International Continence Society (ICS) published a terminology statement on lower urinary tract function in 2002 (Abrams et al 2002a,b). The majority of the following definitions are based on this statement.

Urgency is the complaint of a sudden compelling desire to pass urine which is difficult to defer. Overactive bladder (OAB) syndrome, urge syndrome or urge-frequency syndrome is characterized by urgency with or without urge incontinence, usually with frequency and nocturia. These symptom combinations are suggestive of urodynamically demonstrable detrusor overactivity, but may be due to other forms of urethrovvesical dysfunction. These terms can be used in the absence of proven infection or other obvious pathology.

Daytime frequency is the number of voids recorded during waking hours, and includes the last void before sleep and the first void after waking and rising in the morning. Increased daytime frequency is the complaint by the patient who considers that he/she voids too often during the day.

Nocturia is the complaint that the individual has to wake at night, once or more, to void. In other words, it is the number of voids recorded during a night's sleep; each void is preceded and followed by sleep.

24-h frequency is the total number of daytime voids and episodes of nocturia during a 24-h period.

Bladder pain can be severe and frequently ill defined with radiation to the vagina and rectum. It is often aggravated by bladder distension, sexual intercourse, spicy foods, alcohol and caffeine, and relieved by voiding.

Dysuria is urethral pain during micturition and may be secondary to obvious pathology such as infection or a urethral diverticulum, or less clear causes such as atrophic urethritis or urethral syndrome.

Haematuria is an important symptom that requires urgent evaluation to exclude carcinoma.

PBS is the complaint of suprapubic pain related to bladder filling accompanied by other symptoms such as increased daytime and night-time frequency, in the absence of proven urinary infection or other pathology. The ICS believes this to be a preferable term to 'interstitial cystitis'. Interstitial

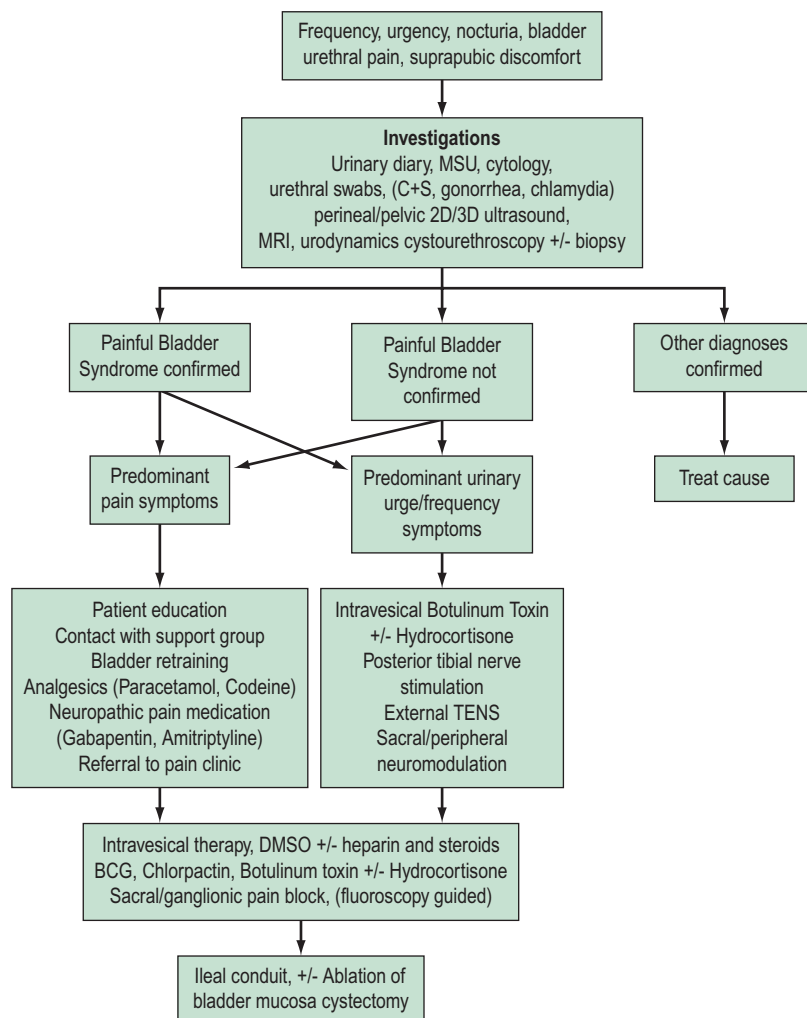

Figure 56.1 Management strategy for women presenting with intractable lower urinary tract symptoms.

MSU, midstream urine sample; 2D, two dimensional; 3D, three dimensional; MRI, magnetic resonance imaging; TENS, transcutaneous electrical nerve stimulation; BCG, bacillus Calmette-Guérin; DMSO, dimethyl sulfoxide; C+S, culture and sensitivity.

cystitis is a specific diagnosis requiring confirmation by the typical cystoscopic and histological features.

Urethral pain syndrome is recurrent episodic urethral pain, usually on voiding, with daytime frequency and nocturia in the absence of proven infection or other pathology.

Prevalence

A population-based study on the prevalence of lower urinary tract symptoms showed that the most commonly reported storage symptom in women is nocturia (54.5%). Urgency occurs in 12.8% and frequency in 7.4% of women. If nocturia is defined as two or more nocturnal micturitions per night, instead of one or more, the prevalence is decreased to 24% (Irwin et al 2006). PBS is a common condition in women, with reported prevalence of 1.7% in those aged under 65 years and 4% in those aged over 80 years. The vast majority of women with PBS have moderate or severe symptoms (Lifford and Curhan 2009).

Aetiology

Irritative bladder symptoms can be caused by a number of conditions originating within the lower urinary tract (Box

56.1). Infection and functional disorders, such as detrusor overactivity or voiding dysfunction, may cause urge symptoms and should be excluded. These conditions should be differentiated from more generalized systemic disorders (e.g. pregnancy, diabetes mellitus, renal disease), pelvic inflammatory disease or gynaecological surgery. A pelvic mass may cause urge-frequency symptoms due to bladder compression.

The aetiology of PBS is poorly understood. Several theories have been proposed over the years, including infection, immunological factors, leaky urothelium due to glycosaminoglycan deficiency, mast cell activation and altered neural function. Consensus is developing regarding epithelial dysfunction, mast cell activation and neurogenic inflammation; all part of a possible inflammatory response (Elgavish 2009).

Assessment

History

A detailed history should include specific questions regarding gynaecological and urinary symptoms. Frequency, urgency and nocturia in association with incontinence are likely to reflect underlying detrusor overactivity. In contrast,

Box 56.1 Non-infective sensory disorders of the lower urinary tract**Inflammatory bladder conditions**

- PBS/interstitial cystitis
- Drug-induced cystitis
- Chemical cystitis
- Eosinophilic cystitis
- Granulomatous cystitis
- Radiation cystitis

Non-malignant conditions affecting the lower urinary tract

- Proliferative
 - Cystitis cystica
 - Cystitis glandularis
- Metaplastic
 - Keratinizing and non-keratinizing squamous metaplasia
 - Intestinal metaplasia
- Other
 - Endometriosis
 - Nephrogenic adenomatosis
 - Amyloidosis

Benign and malignant bladder and urethral tumours

- Papillomas
- Polyps
- Carcinoma *in situ*
- Bladder and urethral carcinoma (primary or secondary)
- Benign and malignant non-epithelial tumours

Miscellaneous

- Bladder or urethral calculi
- Urethrovaginal foreign bodies (e.g. sutures, mesh erosion)
- Urethral diverticulum
- Atrophic urethritis
- Urethral mucosal prolapse
- Urethral caruncle
- Acute and chronic urethral syndromes
- Reiter's syndrome

chronic severe urgency and bladder pain without incontinence are likely to be secondary to intravesical pathology such as infective or non-infective cystitis. A history of present and past medications [e.g. diuretics, tiaprofenic acid (Surgam) and cyclophosphamide], previous urinary tract infection (UTI) and pelvic surgery should be sought. Predisposing or exacerbating factors may include sexual intercourse (e.g. 'honeymoon cystitis'), barrier contraception (e.g. diaphragm, condoms) and contact irritants (e.g. vaginal douches, spermicidal agents). More general irritant factors can include washing powder, soaps and gels.

Voiding dysfunction should be suspected with symptoms of hesitancy, poor urinary stream, straining and incomplete bladder emptying. Impaired bladder emptying due to detrusor underactivity or urethral obstruction may be idiopathic or secondary to neurological disease, pelvic surgery or utero-vaginal prolapse.

Examination

Abdominal examination may reveal a palpable bladder secondary to urinary retention, pelvic mass or bladder tenderness from cystitis. Neurological examination with directed assessment of the S2–4 nerve roots, which innervate the bladder, should be performed. Vaginal examination using a Sims speculum allows visualization of the anterior and posterior walls, and may reveal genital prolapse, atrophy, inflammation or infection. Urethral inspection may reveal a mass, mucosal prolapse or caruncle. Paraurethral masses can be identified on bimanual examination by compressing the urethral and paraurethral tissues against the back of the pubic symphysis; expression of urethral pus suggests a urethral diverticulum.

Investigations**Urinary diary**

A detailed 3-day urinary frequency–volume diary is an important part of the initial and ongoing assessment (Figure 56.2). These diaries are more accurate than patient recall, allowing rapid and accurate diagnosis of urinary frequency, nocturia, estimation of voided volumes, functional bladder capacity, and assessment of episodes of urgency, pain and incontinence as well as their temporal relationship. A diary will also educate the patient regarding voiding habits, and is essential for bladder retraining.

Microbiology

Midstream urine sample (MSU) for microscopy, culture and sensitivity, and cytology will diagnose a UTI, confirming or excluding the presence of leukocytes, nitrites, red blood cells and any abnormal tumour cells shed from a bladder cancer. Isolated haematuria with a negative MSU may be caused by inflammatory cystitis or carcinoma, and is an indication for cystoscopy.

Urethral swabs are indicated where the MSU is negative and there is urethral tenderness, discharge or the patient is sexually active. In these cases, appropriate culture media should also be used for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Other organisms commonly identified include coliforms and *Staphylococcus saprophyticus*. Tuberculosis is still prevalent, especially in developing countries, and should be considered with persistent sterile cystitis and pyuria. Diagnosis is based on a positive Lowenstein–Jensen culture using three early morning urine specimens.

Urodynamics

Urodynamic studies should be considered once infection has been excluded and symptoms have not responded to conservative treatment, especially if urinary incontinence is an associated problem. Uroflowmetry measures the voided volume, and maximum and average flow rates, and also records the voiding pattern. Filling cystometry gives information on bladder sensation, compliance and detrusor contractility, and may identify underlying stress incontinence, detrusor overactivity or voiding dysfunction. A diagnosis of bladder hypersensitivity is based on the following findings at urodynamics: stable bladder, capacity less than 350 ml

URINARY DIARY

NAME.....

UNIT NO.....

WEEK BEGINNING JANUARY 2009.....

CHART NO.....

Instructions

This chart is designed to help us assess and treat your urinary problems. It will only help us to help you if you take time to fill it in accurately.

Please enter the amount each time you pass urine (measured by jug) or drink any liquid.

e.g. 1 cupful = 6 oz. or 175 ml
1 tumblerful = 7 oz. or 200 ml
1 soupbowl = 11 oz. or 300 ml

If you leak urine try to estimate the amount (1 = few drops; 2 = soaked underwear; 3 = emptied bladder). Also note whether you had any warning or urge to pass urine at that time.

Use a blue pen for daytime records and a red pen after you retire to bed.

Figure 56.2 Urinary frequency-volume diary.

Figure 56.3 Transperineal high-frequency ultrasound and corresponding line diagram demonstrating a large urethral diverticulum. U, urethra. (A) The arrows indicate the paraurethral lesion (diverticulum). (B) Enlarged ultrasound image of the diverticulum in (A) demonstrating mixed reflective echogenic pattern.

and urgency at less than 150 ml. Both urodynamic assessment and a urinary diary will give an indication of functional bladder capacity and the severity of bladder hypersensitivity. Women with severe PBS/interstitial cystitis are frequently unable to hold more than 50–100 ml.

Imaging

Imaging of the urinary tract can be performed using ultrasound or contrast radiography, either alone or synchronously with urodynamic assessment [videocystourethrography (VCU)]. VCU demonstrates voiding function and can identify urethral obstruction, a urethral diverticulum or external compression due to fibroids or prolapse. Haematuria in the absence of identifiable uropathogens, negative cystoscopy or recurrent UTI is an indication for assessment of the upper urinary tract using contrast intrave-

nous urography or urinary tract ultrasound. Ultrasound can also determine bladder residual volume and bladder wall thickness, and identify any structural abnormalities, including urethral diverticulae (Figure 56.3) (Doumouchsis et al 2008).

In women with recurrent UTI, 5% have an abnormality of the urinary tract (e.g. calculus, duplex system, tumour). In women with irritative lower urinary tract symptoms and a paraurethral mass, a micturating cystogram or double balloon contrast urethrogram may identify a communicating tract with a urethral diverticulum. Transperineal ultrasound provides comparable information, is less invasive and allows differentiation between solid (e.g. fibroid, lipoma), cystic lesions (diverticulum, Skene's cyst or abscess, Gartner's duct cyst) and vascular lesions (haemangioma, fibroid). Mixed echogenic contents suggest an infected diverticulum or paraurethral abscess.

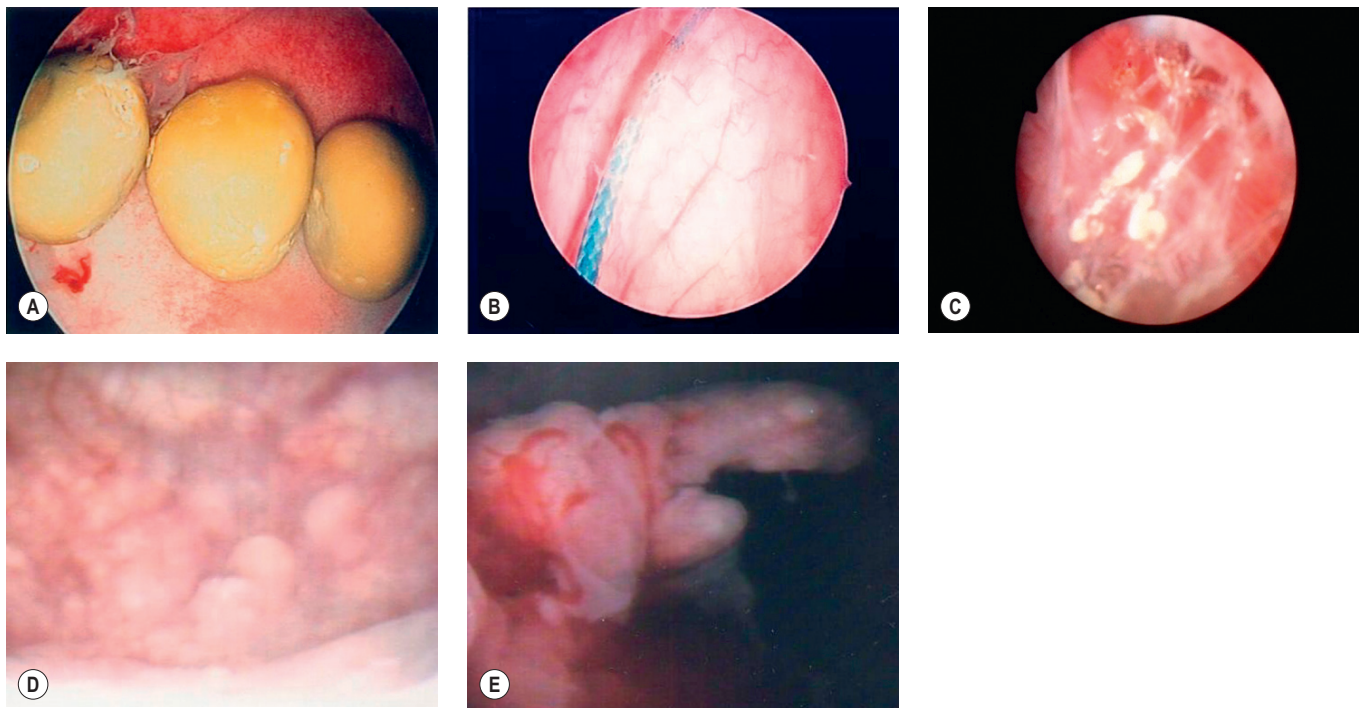

Figure 56.4 Cystoscopy. (A) Bladder calculi. (B) Suture material in bladder. (C) Urethral mesh erosion. (D) Postmenopausal recurrent bacterial cystitis. Squamous metaplasia/cystitis cystica involving trigone and above (benign). Treated with topical oestrogens and rotational antibiotic prophylaxis. (E) Trabeculation, bladder tumour of the right side of bladder wall (malignant). Transurethral resection of bladder tumour undertaken.

Plain abdominal X-ray will demonstrate 90% of calculi present in the kidney, ureters or bladder due to the presence of calcium or cystine. Computed tomography (urogram or magnetic resonance imaging) may be required to provide accurate imaging of upper and lower urinary tract pathology. The automated bladder ultrasound machine is a simple, inexpensive tool used to measure urinary residual volume. However, it does have relatively poor sensitivity for volumes of less than 100 ml or more than 400 ml. In addition, artefacts may be introduced by the presence of pelvic pathology (e.g. uterine fibroids, pelvic haematoma, ovarian cysts) (Cooperberg et al 2000). The automated bladder ultrasound machine is a useful screening tool in older women with urge-frequency syndrome and/or recurrent cystitis with suspected voiding difficulty.

Cystourethroscopy

Evaluation of the lower urinary tract by cystourethroscopy is an essential skill for all gynaecological surgeons, not only in the assessment of urinary symptoms and pain but during pelvic surgery for the prevention and early treatment of bladder and urethral injury. Cystoscopy is undertaken in an inpatient or outpatient setting using a flexible or rigid system. Rigid cystoscopy is well tolerated by women under local anaesthetic in an outpatient setting (Lee et al 2009). Cystoscopy is indicated for haematuria, abnormal urinary cytology, recurrent UTI or persistent symptoms despite conservative treatment. At cystourethroscopy, the lower urinary tract should be carefully visualized using a 70° or 30° scope for the bladder and a 0° scope with Sasche sheath for the urethra. Features such as mucosal trabeculation, bladder diverticula, tumours, squamous metaplasia, bladder calculi

and foreign bodies are readily identifiable (Figure 56.4). Women with misplaced intravesical sutures (e.g. colposuspension), eroded mesh following slings for incontinence or grafts for prolapse surgery, exposed urethral bulking agents or sterile abscess (e.g. Zuidex) may present with urgency, bladder pain and/or recurrent UTI. A biopsy should be taken of any suspicious localized lesions to exclude carcinoma.

Miscellaneous

Renal function, endocrine profile, glucose tolerance test, serum calcium or urinary osmolality tests may be indicated, especially in the presence of polyuria and polydipsia. This is usually detected by a urinary diary. If any of these investigations are positive, referral to an appropriate specialist for further investigation is necessary.

Treatment

For women with idiopathic urge-frequency syndrome, simple patient education with reduction of caffeine, fluid or alcohol intake, adjustment of diuretic or other medications, and bladder retraining with or without anticholinergic agents is effective (50–70%). The aim of bladder retraining is to normalize voiding habits by encouraging increased voided volumes and time between micturitions. If symptoms are severe or do not respond to conservative treatment, further evaluation, particularly with cystourethroscopy, is warranted to identify treatable causes. Cystodistension is not effective in the longer term and may cause bladder perforation. Women with frequency, urgency and bladder pain with reduced functional bladder capacity on urinary diary and

urodynamic assessment may have PBS. Typically, these women will have changes at cystoscopy (petechial haemorrhages on empty and refill, erythema, fissuring).

Painful bladder syndrome/interstitial cystitis

The European Society for the Study of Interstitial Cystitis (ESSIC) recently proposed the term 'bladder pain syndrome/interstitial cystitis' (van de Merwe et al 2008). Guy Hunner first described this condition in 1914, and the mucosal tearing and fissuring which he described as an 'ulcer' carries his name. PBS/interstitial cystitis is a chronic bladder condition seen mainly in women (10:1 female:male ratio). The main presenting symptoms are frequency, urgency, nocturia and bladder pain, which often increase as the bladder fills and reduce after micturition. Pain may be experienced in the urethra, loin area and/or perineum. Chronic pelvic pain, dyspareunia and dysmenorrhoea are also common symptoms, and coexistence with other causes of pelvic pain (e.g. endometriosis) is well recognized. There are cystoscopic and histological features which are considered typical, but in many cases, the diagnosis is one of exclusion, having ruled out specific causes such as infection and malignancy.

OAB shows some similarity in its clinical presentation but without the pain, which is the defining symptom of PBS/interstitial cystitis.

The reported prevalence of PBS/interstitial cystitis varies widely due to different diagnostic criteria. It has been estimated at 18 per 100,000 women in Finland (Oravisto 1975), eight to 16 per 100,000 in the Netherlands (Bade et al 1995), 30 per 100,000 in 1987 in the USA, and 865 per 100,000 women in 1994 in the USA (Rosamilia 2005). Delay between onset of symptoms and diagnosis can be 5–7 years. Leppilahti et al (2005) found that the prevalence of clinically confirmed probable interstitial cystitis in women was 230/100,000 and the prevalence of possible/probable interstitial cystitis was 530/100,000.

The pathophysiology is poorly understood and the condition is considered multifactorial (Nickel 2002). Proposed aetiologies include an infective agent, allergic or autoimmune conditions, 'leaky' urothelium secondary to a defective glycosaminoglycan layer, urinary toxins, lymphatic or vascular abnormalities and neurogenic inflammation. Any of these pathological changes may be a result rather than cause of the disease process. Loss of integrity at the epithelial surface of the bladder, secondary to an infective or other inflammatory insult, has been implicated along with sensory nerve upregulation and enhanced mast cell activation (Sant 2002), resulting in regional neuropathy. Other gynaecological and gastrointestinal manifestations may be present, including pain and voiding symptoms (Nickel 2002).

The ESSIC group (van de Merwe et al 2008) proposed that a diagnosis of PBS should be made on the basis of exclusion of confusable diseases and by the recognition of the specific combination of symptoms and signs of PBS. Confusable diseases include carcinoma, infection, urethral diverticulum, prolapse, endometriosis, OAB and pudendal nerve entrapment. Symptoms and signs for use in diagnostic criteria do not need to be specific. On the contrary, if a specific symptom or sign existed for the target disease, a diagnosis would only require the presence of the specific feature, and diagnostic

criteria would not be necessary. PBS should be diagnosed on the basis of chronic (>6 months) pelvic pain, pressure or discomfort perceived to be related to the urinary bladder, accompanied by at least one other urinary symptom such as persistent urge to void or frequency. Further classification of PBS is based on findings at cystoscopy using hydrodistension and bladder biopsies. Cystoscopic features accepted as positive signs are glomerulations, Hunner's lesions or both (Figure 56.5). Hunner's lesion is 'a circumscribed, reddened mucosal area with small vessels radiating towards a central scar, with a fibrin deposit or coagulum attached. This site ruptures with increasing bladder distension, with petechial oozing of blood from the lesion and mucosal margins in a waterfall manner. A rather typical, slightly bullous edema develops post-distension with varying peripheral extension'. Biopsy findings accepted as positive signs of PBS are inflammatory infiltrates and/or granulation tissue and/or detrusor mastocytosis and/or intrafascicular fibrosis (van de Merwe et al 2008). Only 50% of cases have positive histopathology findings, and the purpose of biopsy is often to exclude malignancy.

As the aetiology of the syndrome is multifactorial, treatment efficacy may vary among different patients, and multiple treatment modalities are often necessary, directed at different disease processes (e.g. bladder retraining, neuromodulation, polypharmacy), if a successful outcome is to be achieved. Although many options are available for controlling symptoms, cures are rare and relapse is common. Symptomatic support by family, medical staff and self-help groups are invaluable. In order to identify the most effective treatment for a patient, they should be tried one at a time. Limited evidence is available from randomized controlled trials. A placebo effect is probably significant in these treatment modalities.

A simple treatment is dietary manipulation. Eliminating substances that may cause bladder inflammation can help some patients (e.g. caffeine, spicy foods). Other non-invasive measures include bladder retraining and relaxation techniques in order to gradually prolong the time periods between voids.

There are several oral or intravesical options with variable efficacy, and to date there is no consensus regarding which treatment is best. Pentosan polysulfate sodium (Elmiron) is a polysaccharide which decreases urothelial permeability by substituting for a defect in the glycosaminoglycan layer. The recommended oral dose is 100 mg three times a day between meals. Response to treatment is likely to be slow, and patients may not notice any benefit until several months of treatment. Antihistamines prevent activation of mast cells. Cimetidine, an H₂ receptor antagonist, has also been tried with variable results. Tricyclic antidepressants have anticholinergic, analgesic and sedative effects on the bladder. Amitriptyline has also shown some benefit. The dose can be increased up to 100 mg. Anticholinergic drugs may be effective, especially if frequency and urgency are predominant symptoms. Oxybutynin has been used orally as well as intravesically. Dimethyl sulfoxide is a chemical solvent that is used intravesically. It penetrates cell membranes and has anti-inflammatory, analgesic and muscle-relaxant properties. It is thought to inhibit mast cells and dissolve collagen. The treatment is repeated at intervals of 2 weeks. Over 50% symptom improvement is common with this

Figure 56.5 Cystoscopic images demonstrating progressive petechial haemorrhaging on bladder emptying under direct vision in a patient with painful bladder syndrome/interstitial cystitis.

treatment, which may be long lasting. Intravesical heparin instillation has also been used, but the evidence for its efficacy is poor. Other medications include bacillus Calmette-Guérin (BCG), hyaluronic acid, chondroitin sulphate and resiniferatoxin.

Botulinum toxin A has been used in the treatment of PBS with variable results. A Cochrane review on intravesical therapy showed that BCG and oxybutynin are reasonably well tolerated, and evidence is most promising for these. Resiniferatoxin has limited efficacy and causes pain, reducing treatment compliance (Dawson and Jamison 2007). Major urological surgery involving ulcer resection, bladder denervation, and partial or total cystectomy with urinary diversion should be considered as a last resort.

Drug-induced cystitis

The bladder is susceptible to the adverse effects of drugs because of the excretion of several drug metabolites in the urine. A history of present and past medications is important as drug-induced cystitis can occur immediately following administration or may manifest many years later. The term 'drug-induced cystitis' is therefore dependent on evidence of the onset of irritative symptoms and inflammatory changes at cystoscopy following drug administration, resolution following withdrawal, and recurrence with readministration of the drug. Implicated drugs include cyclophosphamide, tiaprofenic acid (Surgam), sulphasalazine, fenfluramine, fluoxetine, simvastatin, danazol and a number of non-

steroidal anti-inflammatory drugs. Drugs that cause cystitis should be withdrawn if a patient develops irritative symptoms or haematuria. Adverse effects of cyclophosphamide can be reduced with prophylactic administration of Mesna (2-mercaptoethane sulfonate sodium) and adequate hydration. Mitomycin, doxorubicin or BCG instilled locally to treat bladder tumours can also cause cystitis, contracture and calcification. Their administration should therefore be limited to 1 h/week for a maximum of 8 weeks (Drake et al 1998).

Radiation cystitis

Radiation cystitis may occur as an early or late complication. The bladder can be irradiated intentionally for the treatment of bladder cancer, or incidentally for the treatment of pelvic malignancies. Radiation cystitis is characterized by dysuria and increased urinary frequency (Chuang et al 2008). Acute cystitis is caused by the inflammatory response to radiation, and consists of urgency, frequency, dysuria and haematuria. Chronic cystitis is the end result of the inflammatory process. Ischaemia and fibrosis may result in a small contracted non-functional bladder with severe frequency, urgency and incontinence. Radiation cystitis can range from minor temporary irritative voiding symptoms to severe haematuria, incontinence, fistula formation, necrosis and death. The total single dose, duration of radiotherapy, treatment cycle, preceding surgery, pre-existent infection and previous radiotherapy all influence the risk of radiation cystitis.

Eosinophilic cystitis

Eosinophilic cystitis is a rare inflammatory condition of the bladder which has been associated with allergy, bladder tumours, bladder injury, infections and drugs. It is characterized by the antigen–antibody reaction and probably represents a type 1 hypersensitivity reaction to exogenous allergens. Transmural inflammation of the bladder, predominantly with eosinophils, is followed by fibrosis in the chronic phase. Affected individuals typically have a history of atopy and present with frequency, dysuria, suprapubic pain, haematuria, proteinuria and pyuria. Eosinophiluria occurs in 30% of cases, but up to 50% will have a raised serum eosinophil count. Cystoscopy and biopsy are the gold standard for diagnosis. Medical therapy, such as non-steroidal anti-inflammatory agents or steroids, may provide symptomatic relief, but long-term follow-up is mandatory as the lesion tends to recur (Teegavarapu et al 2005).

Granulomatous cystitis

This condition may arise following bladder resection, bladder biopsy, bacterial infection or BCG instillation, and should be distinguished from tuberculosis. The patient may be asymptomatic or present with haematuria, frequency, urgency and pain. Discrete plaques or nodules may be evident at cystoscopy. At histology, diffuse granulomas or histiocytic inflammation are usually identified.

Proliferative and metaplastic lesions of the bladder

'Brunn's nests', cystitis cystica, cystitis glandularis and squamous metaplasia are common findings at cystoscopy, which are likely to represent normal histological variants. They are usually located on the trigone and anterior wall of the female bladder. Coexistent symptoms of frequency, urgency or bladder pain are more likely to be associated with infection or other inflammatory pathology.

Proliferative cystitis typically starts with 'Brunn's nests', which are clusters of pale yellow cells, 1–5 mm in diameter, within the lamina propria. These lesions are usually confined to the trigone but may be diffuse; differentiation from carcinoma requires biopsy for histological analysis. Cystitis cystica is a result of dilatation of the Brunn's nests within the lamina propria, which are lined by stratified or squamous epithelium, and in cystitis glandularis by columnar epithelium.

Squamous metaplasia is a well-delineated 'white patch' confined to the trigone, and is present in oestrogen-producing women. Keratinizing squamous metaplasia is also known as 'leukoplakia'. It is generally diffuse and associated with recurrent infection and chronic irritation. It often occurs in association with bladder calculi, urethral diverticula or a foreign body. Macroscopically, the affected areas of the bladder have a thickened white and shiny appearance interspersed with areas of bladder inflammation. Bladder biopsies typically demonstrate mature keratinized stratified squamous epithelium. Its clinical significance remains unclear, but has been linked to the development of invasive squamous cell carcinoma. Both synchronous diagnosis of urothelial tumour and subsequent tumour development on

follow-up have been identified. The risk of malignancy is increased in cases with dysplasia as well as extensive keratinization. Lesions should be treated with local transurethral resection. Although dysplasia is considered to be a premalignant condition, there is not enough evidence to identify keratinizing squamous metaplasia of the bladder as premalignant. However, all patients should undergo regular surveillance (Ahmad et al 2008).

Lower urinary tract tumours

Carcinoma *in situ* (CIS) may be asymptomatic or present with microscopic or gross haematuria, urgency, frequency and dysuria. Diagnosis is often delayed because symptoms are attributed to UTI. More than 50% of patients with CIS have coexistent papillary cancer. Cystoscopic appearance varies from normal to erythema or oedema. Histology usually demonstrates abnormal pleomorphic transitional cells confined to the urothelium. Investigation includes urine cultures for fungi and tuberculosis, and cytology studies. Urine cytology is positive in 80–90% of cases. Intravesical BCG instillation is considered the preferred treatment. Surgical resection with radical cystectomy or ablation using transvesical laser or diathermy are indicated for persistent disease, but recurrence or progression to muscle invasion will occur in more than 40% of these women. Chemotherapy, α -interferon and photodynamic therapy are other treatment options for BCG-refractory cases. Outcomes vary and depend on whether CIS is *de novo*, secondary or concomitant to papillary bladder cancer (Nese et al 2009).

The majority of primary invasive lower urinary tract tumours present with painless haematuria or irritative bladder symptoms. UTI is a frequent association. The most common histological type of primary bladder carcinoma is transitional cell (>90%). In the developing world, however, schistosomiasis is associated with an increased incidence of squamous carcinoma. Adenocarcinoma is uncommon but may arise in the embryological remnants of the urachus.

Lower urinary tract calculi

Bladder and urethral calculi in women often arise secondary to a foreign body (e.g. suture material, mesh erosion) or structural abnormalities such as a bladder or urethral diverticulum. They commonly present with recurrent UTI or irritative bladder symptoms. Treatment is directed at removal of the calculus by cystoscopy or lithotripsy, and correction of the underlying abnormality.

Urethral diverticulum

Female urethral diverticula are an uncommon variable in presentation, and the diagnosis is sometimes difficult and delayed. They represent an outpouching of the urethral mucosa through a defect of the periurethral fascia, and may be congenital (embryonic cystic remnants) or more commonly acquired. Obstruction of the periurethral glands, infection and subsequent rupture into the urethral lumen may lead to a urethral diverticulum. Weakening of the periurethral fascia following intraurethral trauma (urethral dilatation), continence surgery or childbirth may result in a

diverticulum. Diverticula may be asymptomatic or present with a variety of symptoms, including urgency, recurrent cystitis, haematuria, urethral discharge, vaginal pain or dyspareunia (Romanzi et al 2000). Depending on the patency of the diverticular ostium, contents may stagnate, predisposing to infection or abscess in up to 30% of cases (El-Mekresh 2000), calculi in 1.5–10% of cases or metaplasia leading to malignancy. Investigations include cystourethroscopy, retrograde urethrography, magnetic resonance imaging, and high-resolution transvaginal or transperineal ultrasound (Rovner 2007).

Urethral pressure profilometry may demonstrate a bifid profile where the urethral diverticular ostium crosses the high-pressure urethral zone.

Surgical excision is necessary in symptomatic women. The aim of surgical repair is to excise the diverticular wall, close the ostium and repair the periurethral fascial defect in layers without tension to reduce the risk of recurrence or fistula formation. In the presence of a large defect or poor tissue integrity, reinforcement of the repair is required. Autologous pubovaginal slings with rectus abdominis fascia or local vaginal, labial or bladder wall flaps have been used. The Martius labial fat graft uses a sleeve of adipose tissue mobilized from the labia majora, still attached to its vascular pedicle. This is rotated and tunnelled under the skin into the vagina (Leach 1991). Complications of diverticulectomy include stricture or scarring, recurrence, stress incontinence, fistula, sloughing, urethral pain and dyspareunia. Stress incontinence is more common where the diverticular ostium crosses the urethral sphincter.

Urethral syndrome

Urethral syndrome is a non-specific group of lower urinary tract symptoms, which include pain (suprapubic or urethral) with urinary frequency and urgency. The pain is typically exacerbated by micturition. The diagnosis is one of exclusion. Investigations should exclude infectious and non-infectious causes of cystitis, inflammation secondary to trauma, foreign bodies, contact irritation or localized para-urethral lesions (Skene's abscess, urethral stricture, diverticulum, tumour), and urethral manifestations of systemic disorders (Reiter's syndrome, Stevens–Johnson syndrome). Cystourethroscopy is necessary to exclude local pathology. An MSU and urethral swab should be performed for microscopy and culture. In women with recent-onset dysuria and

frequency (acute urethral syndrome), and an MSU specimen demonstrating pyuria with less than 10^5 micro-organisms/ml, an infective cause is often identified (Stamm et al 1980). The most common organisms isolated on culture of urinary specimens or urethral swabs include coliforms, *C. trachomatis*, *S. saprophyticus* and *N. gonorrhoeae*. If cultures are negative, empirical antibiotic therapy with doxycycline alone or in combination with a sulphonamide should be considered, and is frequently associated with symptomatic resolution (Latham and Stamm 1984).

In women with chronic urethral symptoms, an infective cause is less likely. In the past, urethral dilatation was frequently performed based on the assumption that the condition was due to urethral obstruction, with 80% of women reporting symptom improvement. Symptomatic improvement is also noted following cystoscopy alone, and urethral dilatation may be associated with urethral fibrosis or damage to the urethral sphincter with secondary stress incontinence. Pharmacological agents (e.g. benzodiazepines) have also been used. Their presumed effect is to reduce urethral spasm, although there is no evidence to support this hypothesis.

Urethral syndrome may represent another variation of chronic pain syndromes which are complex and poorly understood (e.g. PBS, vulvodynia). There is no consensus on appropriate management of this condition. Amitriptyline, used for the treatment of other chronic pain syndromes, is often helpful and also has a beneficial anticholinergic effect. Pharmacological therapy should be combined with education and psychological counselling.

Summary

Sensory disorders of the lower urinary tract are common and frequently unrecognized. This often leads to many years of suffering before an accurate diagnosis is made. This is distressing for both the affected individual and their family, and may be potentially serious. A sound working knowledge of the clinical presentation, differential diagnoses and diagnostic criteria for these conditions is essential for all practising gynaecologists. While some of these disorders have specific and effective therapeutic options, others remain poorly understood. Further research is required to evaluate the pathogenesis of these conditions, as it is likely that effective therapeutic protocols will only be developed when the disease process itself is understood.

KEY POINTS

- 1 Urge-frequency syndrome is common and caused by a wide variety of localized and systemic conditions. A detailed history, examination and sound basic knowledge are required to provide an accurate diagnosis and therapy.
- 2 Frequency–volume diaries are an inexpensive and accurate way to assess symptom severity and response to behavioural therapy.
- 3 Cystoscopic evaluation of the lower urinary tract is an essential skill for all gynaecological surgeons, not only in the assessment of urinary symptoms and pain but during pelvic surgery for the prevention and early treatment of bladder and urethral injury.
- 4 Patient education and access to support networks are important aspects in the management of PBS and other chronic pain syndromes.
- 5 Bladder retraining, and oral and intravesical drug therapy are effective treatments for the management of PDS or urge-frequency syndrome. The role of botulinum toxin A is unclear.
- 6 Where urinary cultures are negative, empirical therapy with antibiotics may result in symptom resolution in women with 'urethral syndrome'.

CLASSIFICATION	880	PREVENTION	893
PRESENTATION	881	KEY POINTS	893

Introduction

A fistula may be defined as an abnormal communication between two or more epithelial surfaces. In the context of gynaecology, we are concerned primarily with fistulae between the genital tract (vagina, cervix, uterus or perineum, in decreasing order of frequency) and either the urinary tract (bladder, urethra or ureter) or the gastrointestinal tract (rectum, colon, anal canal or small bowel).

Multiple or complex fistulae are common, particularly after attempts at surgical repair. Dual involvement of the bowel and urinary tract is regularly seen, and concurrent involvement of, for example, ureter and bladder, or bladder and urethra is often seen in strategically placed or large urinary fistulae. They may also involve an intervening cavity so that the fistulous nature of an inflammatory mass may not be immediately obvious.

Rarer forms may occur, such as a salpingocolic fistula in association with actinomycosis or tuberculosis. Whilst such pathologies are interesting and important as causes of diagnostic confusion and therapeutic difficulty, they are not considered further in this chapter due to their rarity.

Aetiology and Epidemiology

The aetiology of urogenital fistulae is varied, and may be broadly categorized into congenital or acquired, the latter being divided into obstetric, surgical, radiation, malignant and miscellaneous causes. The same factors may be responsible for intestinogenital fistulae, although inflammatory bowel disease is an additional important aetiological factor here. In most developing countries, over 90% of fistulae are of obstetric aetiology, whereas in the UK, approximately 70% follow pelvic surgery (Table 57.1).

Congenital fistulae are strictly outside the scope of this chapter, and readers are advised to refer to Chapter 13

for further information. Some cases of ectopic ureter may discharge into the vagina, and their presentation may be delayed into teens or adult life, hence leading to confusion with acquired fistulae or other causes of incontinence. This occurs particularly if the abnormal ureter is only draining a small or poorly functioning part of the renal tissue. Under these circumstances, the abnormal tissue may be insufficient to show up as a soft tissue shadow on a plain X-ray, and so poorly functional that it is not easily seen on excretion urography. A high index of clinical suspicion is required if the diagnosis is not to be overlooked (Figure 57.1A,B).

Obstetric

The underlying factors responsible for the development of obstetric fistulae may be considered in physical, biosocial, cultural, and geographical or political terms. The basic physical factors responsible for obstetric fistula development include obstructed labour, accidental injury at the time of caesarean section, forceps delivery, craniotomy, symphysiotomy, traditional surgical practices including circumcision and 'gishiri', and complications of criminal abortion.

The overwhelming majority are complications of neglected obstructed labour. During normal labour, the bladder is displaced upwards and the anterior vaginal wall, bladder base and urethra are compressed between the fetal head and the posterior surface of the pubis. No harm results if this occurs for a short time, but in prolonged obstructed labour, the intervening tissues are devitalized by ischaemia. Usually, the anterior vaginal wall and underlying bladder neck are affected, although the area of necrosis is sometimes higher, in which case the anterior lip of the cervix and underlying trigone are involved. Compression of the soft tissues between the sacral promontory and the presenting part may occur at the same time, with necrosis at the posterior vaginal wall and underlying rectum. The devitalized

area separates as a slough usually between the third and 10th day of the puerperium, with resulting incontinence (Figure 57.2).

Accidental injury to the vaginal wall during a difficult operative delivery may involve damage to the underlying bladder wall, particularly if the tissues are devitalized by prolonged pressure. Forcible rotation of the head with Kielland's forceps is particularly liable to produce such an injury by shearing stresses. The bladder is particularly exposed to injury following symphysiotomy if the pubic bones are too

widely separated by forced abduction of the thighs. In these circumstances, the unsupported bladder neck is very likely to be damaged, especially if the head is rotated and extracted with forceps. The posterior wall of the bladder may be accidentally incised during lower segment caesarean section or repair of ruptured uterus, particularly if the bladder is not reflected sufficiently far downwards before the lower segment is opened. During the reflection itself, the bladder may be torn, especially if a previous operation has made it densely adherent to the lower segment. If the bladder injury goes

Figure 57.1 (A) Intravenous urogram from patient presenting with continuous urinary incontinence; a small discrete upper pole element is visible, although the upper pole ureter is not clearly seen. (B) Appearance of vulva with urethral catheter in place, and a ureteric catheter placed in the ectopic ureteric opening just below the external urethral meatus.

undetected at the time, urinary leakage through the abdominal wound soon develops. This is usually followed by incontinence vaginally when the urine finds its way through the uterine incision. The abdominal leakage then dries up as the bladder drains through the resulting vesicocervical fistula. Alternatively, sutures may be passed through the posterior bladder wall during repair of the uterine incision. The appearance of urinary incontinence in these cases is delayed until the intervening bladder tissue caught up in the suture sloughs.

The perineum and posterior vaginal wall are, of course, at risk from even the most straightforward delivery, although primiparity, forceps delivery, birth weight over 4 kg and occipitoposterior position have been found to be significant risk factors associated with third-degree tears (Sultan et al 1994). Even when identified and repaired, this increases the risk of rectovaginal fistula.

Traditional surgical practices are undertaken in up to 98% of women in some parts of Africa (United Nations Population Fund 2007, World Health Organization 2008), and may play a role in the aetiology of both direct 'surgical' and obstetric fistulae. The practices of 'angurya' and 'gishiri' cutting [female genital mutilation (FGM) type IV] (World Health Organization 2008) are commonly employed to treat a wide variety of conditions including obstructed labour, infertility, dyspareunia, dysuria, amenorrhoea, goitre, back-ache and presumed tumour. The traditional cut made with a razor blade or knife through the vaginal introitus is sometimes superficial, but may result in fistula formation (Figure 57.3). Since cuts are usually made by linear incision into healthy tissues, repair is often much easier than for those resulting from pressure necrosis. Tahzib (1983, 1985) reported on the epidemiological determinants of vesicovaginal fistulae in northern Nigeria. In 84% of cases, obstructed labour was the major aetiological factor, 33% had undergone 'gishiri', and this was felt to be the main aetiological factor in 15%.

Figure 57.2 Puerperal patient following prolonged obstructed labour. An area of devitalized tissue is seen on the anterior vaginal wall, about to slough with resultant fistula formation.

Female circumcision has been practised in various forms in much of North Africa, being most prevalent in Ethiopia, Eritrea, Sudan, Egypt, Mali and Guinea, where currently over 75% of women are affected (World Health Organization 2008). The more extreme forms (previously referred to as 'pharaonic circumcision') involve removal of the labial minora (FGM type IIa), and may include removal of the clitoris (FGM type IIb) and labia majora (FGM type IIc) (see Figure 57.4). In FGM type III, the introitus may be reduced to pin-hole size by excision and apposition of the cut edges

Figure 57.3 Vesicovaginal fistula resulting from 'gishiri' cutting (female genital mutilation type IV).

of the labia minora or majora (infibulation) (World Health Organization 2008). Whilst an association between FGM and both vesicovaginal and rectovaginal fistula is recognized (Lovel et al 2000), the strength of the association and the exact mechanisms are less certain and are currently under investigation (World Health Organization 2008).

In considering obstetric fistulae, it is important to consider the social, cultural and geographical influences just as much as the direct physical injury to the lower urinary tract. Obstructed labour is most often due to a contracted pelvis. This usually results from stunting of growth by malnutrition and untreated infections in childhood and adolescence. Where women retain a subservient role in society and standards of education are limited, early marriage and the absence of family planning services result in an early start to childbearing; where first pregnancies occur soon after the menarche, before growth of the pelvis is complete, this also contributes to obstruction in labour.

The influence of these factors is illustrated in the epidemiological studies alluded to earlier. Tahzib (1983) reported that over 50% of the cases of vesicovaginal fistulae seen in northern Nigeria were under 20 years of age, over 50% were in their first pregnancy, and only one in 500 had received any formal education. From the same area, Murphy (1981)

reported that 88% of patients had married at 15 years of age or less, and 33% had delivered their first child before the age of 15 years. However, in different developing world societies, these factors do seem to have variable influence. For example, in south-east Nigeria (Hilton and Ward 1998) and the north-west frontier of Pakistan (World Health Organization 1989), fistula patients seem to be somewhat older and of higher parity; they also appear to have a higher literacy rate, and to be more likely to remain in a married relationship after the development of their fistula (Hilton and Ward 1998). It is likely that the development of fistulae here reflects other biosocial variations (Table 57.2). It is clear that in these populations, even where skilled maternity care is available, uptake may be poor. Mistrust of hospitals is commonplace, antenatal care is poorly attended, and delivery is commonly conducted at home by elderly relatives or unskilled traditional birth attendants. Where labour is prolonged, transfer to hospital may only be used as a last resort.

Surgical

Genital fistula may occur following a wide range of surgical procedures within the pelvis (Table 57.1, Figure 57.5A–F). It is often supposed that this complication results from direct injury to the lower urinary tract at the time of operation. Certainly, on occasions, this may be the case; careless, hurried or rough surgical technique makes injury to the lower urinary tract much more likely. However, of 300 fistulae referred to the author in the UK over the last 20 years, 207 have been associated with pelvic surgery and 147 followed hysterectomy; of these, only seven presented with leakage of urine on the first postoperative day. In other cases, compromise to the blood supply may result in tissue necrosis and subsequent leakage; alternatively, a small pelvic haematoma may develop in association with the vaginal vault, which subsequently becomes infected and discharges with the characteristic puff of haematuria 5–10 days later, with incontinence following shortly thereafter. Recent animal studies suggest that the inadvertent placement of vault sutures into the bladder wall at hysterectomy may not carry as great a risk of fistula formation as previously thought (Meeks et al 1997).

Although it is important to remember that the majority of surgical fistulae follow apparently straightforward hysterectomy in skilled hands, several risk factors may be identified that make direct injury more likely (Table 57.3). Obviously, anatomical distortion within the pelvis by ovarian tumour or fibroid will increase surgical difficulty, and abnormal adhesions between bladder and uterus or cervix following previous surgery or associated with previous sepsis, endometriosis or malignancy may make fistula formation more likely. Preoperative or early postoperative radiotherapy may decrease vascularity, and make the tissues generally less forgiving of poor technique.

Issues of training and surgical technique are, of course, also important. The ability to locate and, if necessary, dissect out the ureter must be part of routine gynaecological training, as should the first aid management of lower urinary tract injury when it arises. The use of gauze swabs to separate the bladder from the cervix at caesarean section or hysterectomy should be discouraged; sharp dissection with knife or scissors does less harm, especially where the tissues are abnormally adherent.

It has recently been shown that there is a high incidence of abnormalities of lower urinary tract function in fistula patients (Hilton 1998); whether these abnormalities ante-date the surgery, or develop with or as a consequence of the fistula, cannot be answered from this data. However, it is likely that patients with a habit of infrequent voiding, or with inefficient detrusor contractility, may be at increased risk of postoperative urinary retention; if this is not recognized early and managed appropriately, the risk of fistula formation may be increased.

Radiation

As noted above, preoperative pelvic irradiation increases the risk of postoperative fistula development, but irradiation itself may be a cause of fistula (Figure 57.5G). The obliterative endarteritis associated with ionizing radiation in therapeutic dosage proceeds over many years, and may be aetiological in fistula formation long after the primary malignancy has been treated. Of the 28 radiation fistulae in the author's series, the fistulae developed at intervals between 1 and 30 years following radiotherapy. Not only does this ischaemia produce the fistulae, it also causes significant damage in the adjacent tissues, so ordinary surgical repair has a high likelihood of failure and modified surgical techniques are required.

Malignancy

The treatment of pelvic malignancy by either surgery or radiotherapy is associated with a risk of fistula development, but tissue loss associated with malignant disease itself may result in genital tract fistula. Carcinoma of cervix, vagina and rectum are the most common malignancies to present in this way. It is relatively unusual for urothelial tumours to present with fistula formation, other than following surgery or radiotherapy. The development of a fistula may be a distressing part of the terminal phase of malignant disease; it

is, nevertheless, one deserving not simply compassion but full consideration of the therapeutic or palliative possibilities.

Inflammatory bowel disease

Inflammatory bowel disease is the most significant cause of intestinogenital fistulae in the UK, although these rarely present directly to the gynaecologist. Crohn's disease is by far the most important, and appears to be increasing in frequency in the Western world. A total fistula rate approaching 40% has been reported, and the involvement of the genital tract in females may be up to 7%.

Ulcerative colitis has a small incidence of low rectovaginal fistulae. Diverticular disease can produce colovaginal fistulae and, rarely, colouterine fistulae, with surprisingly few symptoms attributable to the intestinal pathology. The possibility should not be overlooked if an elderly woman complains of feculent discharge or becomes incontinent without concomitant urinary problems (Figure 57.6).

Miscellaneous

Among other miscellaneous causes of fistulae in the genital tract, the following should be considered.

- Infection
 - Lymphogranuloma venereum
 - Schistosomiasis
 - Tuberculosis
 - Actinomycosis
 - Measles
 - Noma vaginae
- Other
 - Penetrating trauma
 - Coital injury
 - Neglected pessary
 - Other foreign body
 - Catheter-related injury

Prevalence

United Kingdom

The prevalence of genital fistulae obviously varies from country to country and continent to continent as the main causative factors vary. Accurate figures are impossible to obtain since those areas with the highest overall prevalence are also those with the poorest systems of health data col-

lection. UK National Health Service data reported approximately 150 operations for vesicovaginal and urethrovaginal fistula per year in England and Wales in the early 1990s (Hilton 1997). The most recent data from Health Episode Statistics for England suggest an average of 95 operations for vesicovaginal fistula and 10 operations for urethrovaginal fistula per year in England (Department of Health 2009). It is tempting to suggest that this apparent reduction in incidence of fistulae may reflect changes in the practice of

Table 57.3 Risk factors for postoperative fistulae

Risk factor	Pathology	Specific example
Anatomical distortion		Fibroids
		Ovarian mass
Abnormal tissue adhesion	Inflammation	Infection
		Endometriosis
	Previous surgery	Caesarean section
		Cone biopsy
		Colporrhaphy
Impaired vascularity	Malignancy	
	Ionizing radiation	Preoperative radiotherapy
	Metabolic abnormality	Diabetes mellitus
Compromised healing	Radical surgery	
		Anaemia
Abnormality of bladder function		Nutritional deficiency
		Voiding dysfunction

hysterectomy. However, assuming that 50% of urogenital fistulae in the UK follow hysterectomy (as in the author's series), the rate of fistula formation following hysterectomy seems, if anything, to be increasing; from approximately one in 1200 hysterectomies in the period 1990–1991 to 1994–1995 to approximately one in 750 in 2003–2004 to 2007–2008 (Department of Health 2009). Whilst there are other possible explanations, it may be that as fewer hysterectomies are undertaken, those that remain are the more difficult procedures. Studies from Finland suggest a similar rate of posthysterectomy fistulae overall, with approximately one per 1000 abdominal hysterectomies and one per 450 laparoscopic hysterectomies (Harkki-Siren et al 1998). Similarly, ureteric injury may be up to six times as common following laparoscopic hysterectomy compared with open hysterectomy (Harkki-Siren et al 1998), and two to 10 times as common following radical hysterectomy and exenteration (Averette et al 1993, Bladou et al 1995, Emmert and Köhler 1996). Sultan et al (1994) reported that third-degree tears followed 0.6% of vaginal deliveries, and a rectovaginal fistula resulted in 6% of these (one in 3000 deliveries overall).

Figure 57.6 Barium enema from patient complaining of vaginal discharge; demonstrates extensive diverticular disease and obvious colovaginal fistula.

Developing world

In the developing world, many fistula cases are unknown to medical services, being separated from their husbands and ostracized from society. Although the true prevalence in the developing world is unknown, particularly high prevalence rates are reported in Nigeria, Ethiopia, Sudan and Chad. The estimated prevalence in the developing world is one to two per 1000 deliveries, with perhaps 50,000–100,000 new cases each year. Although several units exist in Nigeria, Ethiopia and Sudan, which deal with 100–700 cases per year, this does not come close to meeting the demand, and there are estimated to be perhaps 500,000 to 2 million untreated cases worldwide (Waalwijk and Armiya'u 1993).

Classification

Many different fistula classifications have been described in the literature on the basis of anatomical site or position in relation to meatus or sphincter mechanism; these are often subclassified into simple cases (where the tissues are healthy and access is good) (Figure 57.7A,B) or complicated cases (where there is tissue loss, scarring, impaired access, involvement of the ureteric orifices, or the presence of coexistent rectovaginal fistula) (Figure 57.7C) (Lawson 1978, Waalwijk 1995, Goh 2004). Urogenital fistulae may be classified into urethral, bladder neck, subsymphysial (a complex form involving circumferential loss of the urethra with fixity to bone), midvaginal, juxtacervical or vault fistulae; massive fistulae extending from bladder neck to vault; and vesico-uterine or vesicocervical fistulae. It is interesting to note that whereas over 60% of fistulae in the developing world are

Figure 57.7 (A) Simple posthysterectomy vault vesicovaginal fistula. (B) Same case as in (A) illustrating tissue mobility and ease of access for repair per vaginam. (C) Complex obstetric fistula; a massive vesicovaginal fistula with involvement of both ureteric orifices and coexistent rectovaginal fistula.

midvaginal, juxtacervical or massive (reflecting their obstetric aetiology) (Hilton and Ward 1998), such cases are relatively rare in Western fistula practice; in contrast, 50% of the fistulae managed in the UK are situated in the vaginal vault (reflecting their surgical aetiology). There have been recent calls for classification systems more predictive of outcome (Arrowsmith 2007, Goh et al 2008).

Presentation

Fistulae between the urinary tract and the female genital tract are characteristically said to present with continuous urinary incontinence, both by day and night. In patients with large fistulae, the volume of leakage may be such that they rarely feel any sensation of bladder fullness, and normal voiding may be infrequent. Where there is extensive tissue loss, as in obstetric fistulae from obstructed labour or radiation fistulae, this typical history is usually present, the clinical findings gross, and the diagnosis rarely in doubt. With postsurgical fistulae, for example, the history may be atypical and the orifice small, elusive or occasionally completely invisible. Under these circumstances, the diagnosis can be much more difficult, and a high index of clinical suspicion must be maintained.

Occasionally, a patient with an obvious fistula may deny incontinence, and this is presumed to reflect the ability of the levator ani muscles to occlude the vagina below the level of the fistula. Some patients with vesicocervical or vesico-uterine fistula following caesarean section may maintain continence at the level of the uterine isthmus, and complain of cyclical haematuria at the time of menstruation, or menouria (Falk and Tancer 1956, Youssef 1957). In other cases, patients may complain of little more than a watery

vaginal discharge, or intermittent leakage, which seems posturally related. Leakage may appear to occur specifically on standing or on lying supine, prone, or in left or right lateral positions, presumably reflecting the degree of bladder distension and the position of the fistula within the bladder; such a pattern is most unlikely to be found with ureteric fistulae.

Although in the case of direct surgical injury, leakage may occur from the first postoperative day, in most surgical and obstetric fistulae, symptoms develop between 5 and 14 days after the causative injury; however, the time of presentation may be quite variable. This will depend, to some extent, on the severity of symptoms, but as far as obstetric fistulae in the developing world are concerned, is determined more by access to health care. In a review of cases from Nigeria, the average time for presentation was over 5 years, and in some cases over 35 years, after the causative pregnancy (Hilton and Ward 1998).

Urethrovaginal fistulae distal to the sphincter mechanism will often be asymptomatic and require no specific treatment. Some may lead to obstruction, and are more likely to present with postmicturition dribbling than other types of incontinence; they can therefore be very difficult to recognize. More proximally situated urethral fistulae are perhaps most likely to present with stress incontinence, since bladder neck competence is frequently impaired.

Ureteric fistulae occur from similar aetiologies to bladder fistulae, and the causative mechanism may be one of direct injury by incision, division or excision, or of ischaemia from strangulation by suture, crushing by clamp or stripping by dissection (Yeates 1987). The presentation may therefore be similarly variable. With direct injury, leakage is usually apparent from the first postoperative day. Urine output may be physiologically reduced for some hours following surgery,

and if there is significant operative or postoperative hypotension, oliguria may persist longer. However, once renal function is restored, leakage will usually be apparent promptly. With other mechanisms, obstruction is likely to be present to a greater or lesser degree, and the initial symptoms may be of pyrexia or loin pain, with incontinence only occurring after sloughing of the ischaemic tissue, from around 5 days up to 6 weeks later. On occasion, the reverse pattern may be seen, with apparent relief of leakage resulting from the development of obstruction as scarring in the ureter proceeds (Figure 57.8A).

With intestinal fistulae, the history may be much more misleading. A small communication with the large bowel may only cause an offensive discharge. Even fistulae of obstetric origin may be rendered relatively asymptomatic by the cicatrization of the vagina, which occurs following sloughing. A small high posterior horseshoe-shaped fistula may only become apparent during division of constricting bands for the repair of a vesicovaginal fistula. Most typically, however, patients will complain of incontinence of liquid stool, and flatus, and whilst they may often be unsure about whether stool is from the vagina or anus, the sensation of flatus from the vagina is rarely misinterpreted.

Investigations

If there is suspicion of a fistula but its presence is not easily confirmed by clinical examination with a Sims' speculum, further investigation will be necessary to confirm or fully exclude the possibility. Even where the diagnosis is clinically obvious, additional investigation may be appropriate for full evaluation prior to deciding treatment.

Microbiology

Urinary infection is surprisingly uncommon in fistula patients, although urine culture should be undertaken and appropriate antibiotic therapy instituted, especially where there have been previous attempts at surgery. Urine culture is not easily obtained when a fistula produces severe incontinence, but a pipette may be used to obtain a small intravesical sample for investigation.

Dye studies

When the diagnosis is in doubt, it is important to confirm that the discharge is urinary and that the leakage is extra-urethral rather than urethral, and to establish the site of leakage. Although other imaging techniques undoubtedly have a role (see below), carefully conducted dye studies remain the investigation of first choice.

Excessive vaginal discharge, or the drainage of serum from a pelvic haematoma following surgery, may simulate a urinary fistula. If the fluid is in sufficient quantity to be collected, biochemical analysis of its urea content in comparison to that of urine and serum will confirm its origin. Phenazopyridine is no longer available in the UK, although it has previously been used orally (200 mg tds) to stain the urine and hence confirm the presence of a fistula; alternatively, indigo carmine may be used intravenously for the same purpose. The identification of the site of a fistula

is best carried out by the instillation of coloured dye (methylene blue or indigo carmine) into the bladder via catheter with the patient in the lithotomy position. The traditional 'three swab test' has its limitations and is not recommended; the examination is best carried out with direct inspection, and multiple fistulae may be located in this way. It is important to be alert for leakage around the catheter, which may spill back into the vagina creating the impression of a fistula. It is also important to ensure that adequate distension of the bladder occurs, as some fistulae do not leak at small volumes; conversely, some fistulae with an oblique track through the bladder wall may leak at small volumes but not at capacity. If leakage of clear fluid continues after dye instillation, a ureteric fistula is likely; previously, this could be confirmed by a 'two dye test', using phenazopyridine to stain the renal urine, and methylene blue to stain the bladder contents (Raghavaiah 1974). However, intravesical followed by intravenous injection of dye may be required nowadays.

Dye tests are less useful for intestinal fistulae, although a carmine marker taken orally may confirm their presence. Rectal distension with air via a sigmoidoscope may be of more value; if the patient is kept in a slight head-down position and the vagina filled with saline, the bubbling of any air leaked through a low fistula may be detected.

Imaging

Excretion urography

Although intravenous urography is a particularly insensitive investigation in the diagnosis of vesicovaginal fistula, knowledge of upper urinary tract status may have a significant influence on treatment measures applied, and intravenous urography or computed tomography urogram should be looked on as an essential investigation for any suspected or confirmed urinary fistula (Figure 57.8A,B). Compromise to ureteric function is a particularly common finding when a fistula occurs in relation to malignant disease or its treatment (by radiation or surgery).

Dilatation of the ureter is characteristic in ureteric fistula, and its finding in association with a known vesicovaginal fistula should raise suspicion of a complex ureterovesicovaginal lesion. Whilst essential for the diagnosis of ureteric fistula, urography is not completely sensitive, although the presence of a periureteric flare is highly suggestive of extravasation at this site (Figure 57.8B).

Retrograde pyelography

Retrograde pyelography is a more reliable way of identifying the exact site of a ureterovaginal fistula, and may be undertaken simultaneously with either retrograde or percutaneous catheterization for therapeutic stenting of the ureter (see below) (Figure 57.8C).

Cystography

Cystography is not particularly helpful in the basic diagnosis of vesicovaginal fistulae, and a dye test carried out under direct vision is likely to be more sensitive. It may, however, be useful in achieving a diagnosis in complex fistulae (Figure 57.8D), or vesicouterine fistulae, where a lateral view may

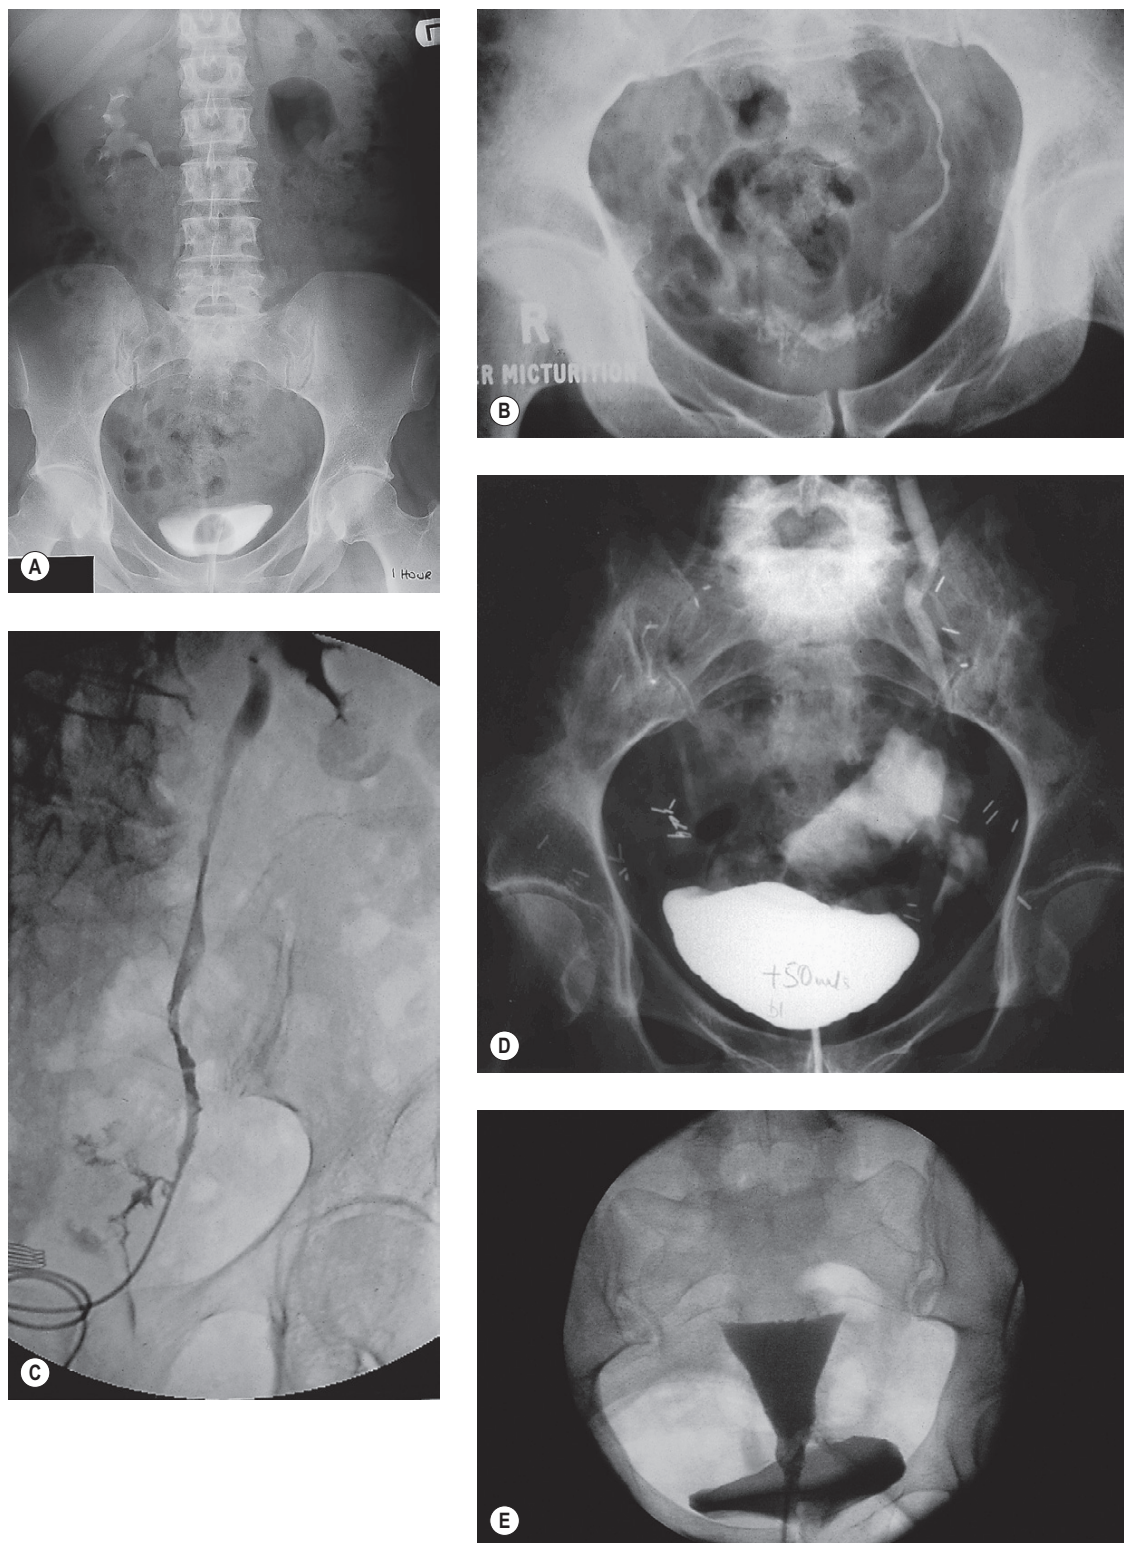

Figure 57.8 (A) Intravenous urogram in a patient who presented with incontinence following hysterectomy, presumed initially to be due to a vesicovaginal fistula. Apparent resolution of the leakage following catheterization was, in fact, due to progressive obstruction above the level of a ureterovaginal fistula. (B) Intravenous urogram showing periureteric flare typical of ureterovaginal fistula. (C) Retrograde pyelogram demonstrating ureterovaginal fistula. (D) Intravenous urogram (with simultaneous cystogram) demonstrating a complex surgical fistula occurring after radical hysterectomy. After further investigation including cystourethroscopy, sigmoidoscopy, barium enema and retrograde cannulation of the vaginal vault to perform fistulography, the lesion was defined as an ureterocolovesicovaginal fistula. (E) Hysterosalpinogram in patient with vesicocervical fistula following caesarean section.

show the cavity of the uterus filled with radiopaque dye behind the bladder.

Fistulography

This is a special example of the X-ray technique commonly referred to as 'sinography'. For small fistulae, a ureteric catheter is suitable, although if the hole is large enough a small Foley catheter may be used to deliver the radio-opaque dye; this is of particular value for fistulae for which there is an intervening abscess cavity. If a catheter will pass through a small vaginal aperture into an adjacent loop of bowel, its nature may become apparent from the radiological appearance of the lumen and haustrations, although further imaging studies are usually required to demonstrate the underlying pathology.

Colpography and hysterosalpingography

If a fistula opening cannot be identified directly, colpography or hysteroscopy may occasionally be helpful. If a large Foley catheter with a large balloon is distended in the lower vagina, injection of a non-viscous opaque medium under pressure may outline a fistulous track to an adjacent organ. However, failure to demonstrate a fistula by this means does not exclude its presence. If a patient with a vesicouterine fistula has no history of incontinence but complains of cyclical haematuria, contrast studies carried out through the uterus (hysterosalpingography) may be more rewarding than cystography. Again, a lateral view is necessary to detect the anterior leak (Figure 57.8E).

Barium enema, barium meal and follow-through

Either or both of these may be required for evaluation of the intestinal condition when an intestinal fistula is present above the anorectum. Aside from confirming the presence of a fistula, evidence of malignant or inflammatory disease may be identified.

Ultrasound, computed tomography and magnetic resonance imaging

These may occasionally be appropriate for the complete assessment of complex fistulae. Endoanal ultrasound and magnetic resonance imaging are particularly useful in the investigation of anorectal and perineal fistulae.

Examination under anaesthesia

Careful examination, if necessary under anaesthetic, may be required to determine the presence of a fistula, and is deemed by several authorities to be an essential preliminary to definitive surgical treatment (Chassar Moir 1967, Lawson 1978, Jonas and Petri 1984, Lawson and Hudson 1987). A malleable silver probe is invaluable for exploration of the vaginal walls, and tissue forceps or plastic surgical skin hooks are helpful to put tension on the tissues for the identification of small fistulae. If the probe passes directly into the rectum, it may be felt digitally or seen via the proctoscope. In the bladder or urethra, it may be identified by a metallic click against a silver catheter, or seen by a cystoscope; in either case, the diagnosis is then obvious.

It is also important at the time of examination to assess the available access for repair vaginally, and the mobility of the tissues (Figure 57.7A,B). The decision between the vaginal and abdominal approaches to surgery is thus made; when the vaginal route is chosen, it may be appropriate to select between the more conventional supine lithotomy with a head-down tilt, and the prone (reverse lithotomy) with head-up tilt (Figure 57.9). This may be particularly useful in allowing the operator to look down on to bladder neck and subsymphysial fistulae, and is also of advantage in some massive fistulae in encouraging the reduction of the prolapsed bladder mucosa (Lawson 1967).

Endoscopy

Cystoscopy

Although some authorities suggest that endoscopy has little role in the evaluation of fistulae, it is the author's practice to perform cystourethroscopy in all but the largest defects (Figure 57.10). Although in some obstetric and radiation fistulae, the size of the defect and the extent of tissue loss and scarring may make it difficult to distend the bladder, much useful information is still obtained. The exact level and position of the fistula should be determined, and its relationship to the ureteric orifices and bladder neck are particularly important. With urethral and bladder neck fistulae, the failure to pass a cystoscope or sound may indicate that there has been circumferential loss of the proximal urethra; a circumstance which is of considerable importance in determining the appropriate surgical technique and the likelihood of subsequent urethral incompetence. Similar considerations may apply to investigation of the lower bowel following major obstetric injuries in which segmental circumferential loss of the upper rectum may have occurred.

The condition of the tissues must be assessed carefully. Persistence of slough means that surgery should be deferred, and this is particularly important in obstetric and postradiation cases. Biopsy from the edge of a fistula should be taken in radiation fistulae, if persistent or recurrent malignancy is suspected. Malignant change has been reported in a long-standing benign fistula, so where there is any doubt at all

Figure 57.9 Patient in prone (reverse lithotomy) position with head-up tilt in preparation for repair of a fixed subsymphysial fistula.

Figure 57.10 Endoscopic appearance of (A) vesicovaginal fistula following total abdominal hysterectomy, (B) urethrovaginal fistula following midurethral tape procedure.

about the nature of the tissues, biopsy should be undertaken (Hudson 1968). In areas of endemicity, evidence of schistosomiasis, tuberculosis and lymphogranuloma may become apparent in biopsy material, and again it is important that specific antimicrobial treatment is instituted prior to definitive surgery. If calculi are identified clinically, radiologically or endoscopically in the bladder, vaginal vault or diverticulum, their removal prior to any attempt at surgical correction is essential.

Sigmoidoscopy and proctoscopy

These examinations are important for the diagnosis of inflammatory bowel disease, which may not have been suspected before the occurrence of a fistula. Biopsies of the fistula edge or any unhealthy looking area should always be obtained.

Management

Immediate management

Before epithelialization is complete, an abnormal communication between viscera will tend to close spontaneously, provided that the natural outflow is unobstructed. Normal continence mechanisms, however, involve the intermittent physiological contraction of urethral and anal sphincters (see Chapter 50). As a result, although spontaneous closure of genital tract fistulae does occur, it is the exception rather than the rule. Bypassing the sphincter mechanisms, or diverting flow around the fistula (e.g. by urinary catheterization or defunctioning colostomy), may encourage closure.

The early management is of critical importance, and depends on the aetiology and site of the lesion. If surgical trauma is recognized within the first 24 h post operatively, immediate repair may be appropriate, provided that extravasation of urine into the tissues has not been great. The majority of surgical fistulae are, however, recognized between 5 and 21 days post operatively, and these should be treated with continuous bladder drainage. It is worth persisting with

this line of management in vesicovaginal or urethrovaginal fistulae for 6–8 weeks since spontaneous closure may occur within this period (Davits and Miranda 1991). Although only 8% of the fistulae in the author's series are known to have healed with catheter drainage, it is possible that the actual rate of spontaneous healing in surgical fistulae is as high as 20%.

Obstetric fistulae developing after obstructed labour should also be treated by continuous bladder drainage (Waldijk 1994a), combined with antibiotics to limit tissue damage from infection. Indeed, if a patient is known to have been in obstructed labour for any significant length of time, or is recognized to have areas of slough on the vaginal walls in the puerperium, or has any indication of urine leakage, prophylactic catheterization should be undertaken; with this approach, spontaneous healing has been reported in up to 28% of cases (Waldijk 1997). If sloughing of the rectal wall has also occurred, faecal discharge will adversely affect spontaneous healing, and temporary defunctioning colostomy should be performed.

The management of ureterovaginal fistulae is beyond the skill of most gynaecologists, and even those with specialist skills in urogynaecology are likely to liaise with urological and radiological colleagues in this situation. Whilst in the past, ureteric reimplantation has been looked on as the preferred approach in most cases, the use of stents inserted either in retrograde (endoscopically) or antegrade (percutaneously) fashion is successful in the majority of cases unless there is complete obstruction (Chang et al 1987, Schwartz and Stoller 2000). Where stenting cannot be achieved, or does not result in closure of the fistula, definitive surgery should be undertaken at 4–6 weeks, unless progressive calyceal dilatation or impairment of function demands earlier intervention.

The immediate management of obstetric third-degree tears has traditionally been thought to lead to good outcome. Recent data suggest that approximately half of patients sustaining such injuries will have subsequent defaecatory symptoms as a result of sphincter disruption rather than denervation, and 6% may end up with rectovaginal fistulae

(Sultan et al 1994). It has not been investigated whether primary repair by a more experienced surgeon or delayed repair would improve outcome.

It is important to appreciate that some fistulae may be associated with minimal symptoms, and even if persistent, these may not require surgical treatment. Small distal urethrovaginal fistulae, uterovesical fistulae with menouria and some low rectovaginal fistulae may fall into this category.

Palliation and skin care

During the waiting period between diagnosis and repair, incontinence pads should be provided in generous quantities so that patients can continue to function socially to some extent. Fistula patients usually leak much greater quantities of urine than those with urethral incontinence from whatever cause, and this needs to be recognized in terms of provision of supplies.

The vulval skin may be at considerable risk from amniacal dermatitis, and liberal use of silicone barrier cream should be encouraged. Steroid therapy has been advocated in the past as a means of reducing tissue oedema and fibrosis, although these benefits are refuted and there may be a risk of compromise to subsequent healing (Jonas and Petri 1984). Local oestrogen has been recommended by some authors (Kelly 1983, Jonas and Petri 1984), and whilst empirically, one might expect benefit in postmenopausal women or those obstetric fistula patients with prolonged amenorrhoea, the evidence for this is lacking.

Nutrition

Due to social ostracism and the effects of prolonged sepsis, patients with obstetric fistulae may also suffer from malnutrition and anaemia. To maximize the prospects for postoperative healing, it is essential that the general health of the patient should be optimized. Where there is severe inflammatory bowel disease, the question of an elemental diet or even total parenteral nutrition may need to be considered in consultation with the gastroenterologist involved.

Physiotherapy

Obstetric fistulae are commonly associated with lower limb weakness, foot drop and limb contracture. In a group of 479 patients studied prospectively, 27% had signs of peroneal nerve weakness at presentation, and a further 38%, whilst having no current signs, gave a history of relevant symptoms (Waldijk and Elkins 1994). Early involvement of the physiotherapist in preoperative management and rehabilitation of such patients is essential.

Antimicrobial therapy

In tropical countries, the treatment of malaria, typhoid, tuberculosis and parasitic infections should be rigorously undertaken before elective surgery. There is no evidence of benefit from prophylactic antibiotics in the management of obstetric fistulae (Tomlinson and Thornton 1998). Opinions differ on the desirability of prophylactic antibiotic cover for surgery in the developed world, with some avoiding their use other than in the treatment of specific infection, and

some advocating broad-spectrum treatment in all cases. The author's current practice is for single-dose prophylaxis with co-amoxiclav in urinary fistulae, and 5 days cover for intestinal fistulae using metronidazole and cefuroxime. Only symptomatic urinary tract infections need to be treated in the catheterized patient.

Bowel preparation

Although surgeons vary in the extent to which they prepare the bowel prior to rectovaginal fistula repair, it is the author's preference to carry out formal preparation in all cases of intestinogenital fistula, whatever the level of the lesion. A low-residue diet should be advised for 1 week prior to admission, followed by a fluid-only diet for 48 h before surgery. Polyethylene glycol 3350 (Kleneprep), four sachets in 4 l of water over a 4-h period, or sodium picosulphate (Picolax) 10 mg repeated after 6 h is given orally on the day before operation. Bowel wash-out should be carried out on the evening before surgery, and if bowel content is not completely clear, this should be repeated on the morning of surgery.

Counselling

Surgical fistula patients are usually previously healthy individuals who entered hospital for what was expected to be a routine procedure, and they end up with symptoms infinitely worse than their initial complaint. Obstetric fistula patients in the developing world are social outcasts. In both situations, therefore, these women are invariably devastated by their situation; significant impact on their mental health has been objectively confirmed (Browning et al 2007). It is vital that they understand the nature of the problem, why it has arisen, and the plan for management at all stages. Confident but realistic counselling by the surgeon is essential, and the involvement of nursing staff or counsellors with experience of fistula patients is also highly desirable. The support given by previously treated sufferers can also be of immense value in maintaining patient morale, especially where a delay prior to definitive treatment is required.

General principles of surgical treatment

Details of individual operations are outside the scope of this chapter, and readers wishing for further information about this aspect of fistula management are referred to operative surgical texts or more specific texts on the subject (Chassar Moir 1967, Lawson and Hudson 1987, Zacharin 1988, Mundy 1993, Waldijk 1994b).

Timing of repair

The timing of surgical repair is perhaps the single most contentious aspect of fistula management. Whilst shortening the waiting period is of both social and psychological benefit to what are always very distressed patients, one must not trade these issues for compromise to surgical success. The benefit of delay is to allow slough to separate and inflammatory change to resolve. In both obstetric and radiation fistulae, there is considerable sloughing of tissues, and it is imperative that this should have settled before repair is undertaken.

In radiation fistulae, it may be necessary to wait 12 months or more. In obstetric cases, most authorities suggest that a minimum of 3 months should be allowed to elapse, although Waaldijk (1994a) has advocated surgery as soon as slough is separated.

With surgical fistulae, the same principles should apply, and although the extent of sloughing is limited, extravasation of urine into the pelvic tissues inevitably sets up some inflammatory response. Although early repair is advocated by several authors (Iselin et al 1998), most would agree that 10–12 weeks after surgery is the earliest appropriate time for repair.

Pressure from patients to undertake repair at the earliest opportunity is always understandably great, but never more so than in the case of previous surgical failure. Such pressure must, however, be resisted, and 8 weeks is the minimum time that should be allowed between attempts at closure.

Route of repair

Many urologists advocate an abdominal approach for all fistula repairs, claiming the possibility of earlier intervention and higher success rates in justification. Others suggest that all fistulae can be successfully closed by the vaginal route (Waaldijk 1994b). Such arguments have little merit, and both approaches have their place. Surgeons involved in fistula management must be capable of both approaches, and have the versatility to modify their techniques to select that most appropriate to the individual case. Where access is good and the vaginal tissues are sufficiently mobile, the vaginal route is usually most appropriate. If access is poor and the fistula cannot be brought within reach, the abdominal approach should be used. Although such difficulties can sometimes be handled vaginally, an abdominal procedure may be used to advantage where there is concurrent involvement of ureter or bowel in a surgical fistula.

Overall, more surgical fistulae are likely to require an abdominal repair than obstetric fistulae, although in the author's series of cases from the UK, and those reviewed from Nigeria, two-thirds of cases were satisfactorily treated by the vaginal route, regardless of aetiology (Table 57.4).

Instruments

All operators have their own favoured instruments, although those described in the treatise by Chassar Moir (1967) and Lawson (1967) are eminently suitable for repair by any route (Figure 57.11).

Dissection

Great care must be taken over the initial dissection of the fistula, and one should probably take as long over this as over the repair itself. Preliminary infiltration with 1 : 200,000 solution of adrenaline may help to separate planes and reduce oozing. The fistula should be circumcised in the most convenient orientation, depending on size and access. All things being equal, a longitudinal incision should be made around urethral or midvaginal fistulae, so that during repair, sutures tend to close the bladder neck; conversely, vault fistulae are better handled by a transverse elliptical incision, so that sutures do not tend to approximate the ureters during repair (Figure 57.12A).

The tissue planes are often obliterated by scarring, and dissection close to a fistula should therefore be undertaken with a scalpel or scissors (Figure 57.12B). Sharp dissection is easier with counter traction applied by skin hooks, tissue forceps or retraction sutures. Blunt dissection with small

Figure 57.12, cont'd

pledgets may be helpful once the planes are established, and provided one is away from the fistula edge. Wide mobilization should be performed, so that tension on the repair is minimized (Figure 57.12C).

There are arguments over the benefits of excision of the fistula track itself. Excision of the bladder walls is probably unwise, as it enlarges the defect and may increase the amount of bleeding into the bladder. However, limited excision of the scarred vaginal wall is usually appropriate (Figure 57.12D).

Bleeding is rarely troublesome with vaginal procedures, except occasionally with proximal urethrovaginal fistulae. Diathermy is best avoided to prevent further devascularization of tissues, and pressure or under-running sutures are preferred.

Suture materials

Although a range of suture materials have been advocated over the years, and a range of opinions still exist, the author's view is that absorbable sutures should be used throughout all urinary fistula repair procedures. Polyglactin (Vicryl) 2/0 suture on a 25-mm heavy tapercut needle is preferred for both the bladder and vagina, and polydioxanone (PDS) 4/0 on a 13-mm round-bodied needle is used for the ureter. 3/0 sutures on a 30-mm round-bodied needle are used for bowel surgery, polydioxanone (PDS) for the small bowel, and either PDS or braided polyamide (Nurolon) for large bowel reanastomosis.

Testing the repair

The closure must be watertight and should be tested at the end of vaginal repairs by the instillation of dye into the bladder under minimal pressure; a previously unsuspected second fistula is occasionally identified this way. Testing after abdominal procedures is impractical.

Specific repair techniques

Vaginal procedures

Dissection and repair in layers

There are two main types of closure technique applied to the repair of urinary fistulae: the classical saucerization technique described by Sims (1852), and the much more commonly used dissection and repair in layers. Sutures must be placed with meticulous accuracy in the bladder wall, with care being taken not to penetrate the mucosa, which should be inverted as far as possible. The repair should be started at either end, working towards the midline, so that the least accessible aspects are sutured first (Figure 57.12E). Interrupted sutures are preferred and should be placed approximately 3 mm apart, taking as large a bite of tissue as feasible. Stitches that are too close together, or the use of continuous or purse-string sutures, tend to impair blood supply and interfere with healing. Knots must be secure with three hitches, so that they can be cut short leaving the minimum amount of material within the body of the repair.

With dissection and repair in layers, the first layer of sutures in the bladder should invert the edges (Figure 57.12E); the second adds bulk to the repair by taking a wide bite of bladder wall, but also closes off dead space by catching the back of the vaginal flaps (Figure 57.12F). After testing the repair (Figure 57.12G) (see below), a third layer of interrupted mattress sutures is used to evert and close the vaginal wall, consolidating the repair by picking up the underlying bladder wall (Figure 57.12H).

Saucerization

The saucerization technique involves converting the track into a shallow crater, which is closed without dissection of bladder from vagina using a single row of interrupted sutures.

The method is only applicable to small fistulae and perhaps residual fistulae after closure of a larger defect; in other situations, the technique does not allow secure closure without tension.

Vaginal repair procedures in specific circumstances

The conventional dissection and repair in layers as described above is entirely appropriate for the majority of midvaginal fistulae, although modifications may be necessary in specific circumstances. In juxtacervical fistulae in the anterior fornix, vaginal repair may be feasible if the cervix can be drawn down to provide access. Dissection should include mobilization of the bladder from the cervix. The repair must be undertaken transversely to reconstruct the underlying trigone and prevent distortion of the ureteric orifices.

Vault fistulae, particularly those following hysterectomy, can usually be managed vaginally. The vault is incised transversely, and mobilization of the fistula is often aided by deliberate opening of the pouch of Douglas (Lawson 1972). The peritoneal opening does not need to be closed separately, but is incorporated into the vaginal closure.

With subsymphysial fistulae involving the bladder neck and proximal urethra as a consequence of obstructed labour, tissue loss may be extensive, and fixity to underlying bone is a common problem. The lateral aspects of the fistula require careful mobilization to overcome disproportion between the defect in the bladder and the urethral stump. A racquet-shape extension of the incision facilitates exposure of the proximal urethra. Although transverse repair is often necessary, longitudinal closure gives better prospects for urethral competence.

Where there is substantial urethral loss, reconstruction may be undertaken using the method described by Chassar Moir (1967) or Hamlin and Nicholson (1969). A strip of anterior vaginal wall is constructed into a tube over a catheter. Plication behind the bladder neck is probably important if continence is to be achieved. The interposition of a labial fat or muscle graft not only fills up the potential dead space, but also provides additional bladder neck support and improves continence by reducing scarring between bladder neck and vagina.

With very large fistulae extending from bladder neck to vault, the extensive dissection required may produce considerable bleeding. The main surgical difficulty is to avoid the ureters. They are usually situated close to the superolateral angles of the fistula, and if they can be identified, they should be catheterized (Figure 57.8). Straight ureteric catheters passed transurethrally or double pigtail catheters may be useful in directing the intramural portion of the ureters internally; nevertheless, great care must be taken during dissection.

Radiation fistulae present particular problems in that the area of devitalized tissue is usually considerably larger than the fistula itself. Mobilization is often impossible, and if repair in layers is attempted, the flaps are likely to slough; closure by colpocleisis is therefore required. Some have advocated total closure of the vagina, although it is preferable to avoid dissection in the devitalized tissue entirely and to perform a lower partial colpocleisis converting the upper vagina into a diverticulum of the bladder. It is usually necessary to fill the dead space below this with an interposition graft (see below).

Abdominal procedures

Transvesical repair

Repair by the abdominal route is indicated when high fistulae are fixed in the vault and are therefore inaccessible by the vaginal route. Transvesical repair has the advantage of being entirely extraperitoneal. It is often helpful to elevate the fistula site by a vaginal pack, and the ureters should be catheterized under direct vision. The technique of closure is similar to that of the transvaginal flap-splitting repair, except that for haemostasis, the bladder mucosa is closed with a continuous suture.

Transperitoneal repair

It is often said that there is little place for a simple transperitoneal repair, although a combined transperitoneal and transvesical procedure is favoured by urologists and is particularly useful for vesicouterine fistulae following caesarean section. A midline split is made in the vault of the bladder; this is extended downwards in a racquet shape around the fistula. The fistulous track is excised, and the vaginal or cervical defect is closed in a single layer. The bladder is then closed in two layers.

For ureteric fistulae not manageable by stenting, reimplantation is considered preferable to reanastomosis of the ureter itself, which carries a greater risk of stricture. Several techniques are described for ureteroneocystostomy, and the most appropriate will depend on the level of the fistula and the nature of the antecedent pathology. The most widely used techniques are direct reimplantation using a psoas hitch, or the creation of a flap of bladder wall (the Boari-Ockerblad technique). There are few lesions which are too high for this approach, although where there is significant deficiency, it may be necessary to perform an end-to-side anastomosis between the injured ureter and the good contralateral ureter (i.e. a ureteroureterostomy), or to interpose a loop of small bowel.

Interposition grafting

Several techniques have been described to support fistula repair in different sites, although the precise role of such grafts is unclear. Some claim that the interposed tissue may serve to create an additional layer in the repair, to fill dead space and to bring in new blood supply to the area, and hence may be of particular value where there is sphincter involvement, and in multiple or recurrent fistulae (Rangnekar et al 2000) or following radiotherapy (Kircuta 1965). Others, however, have questioned their value (Browning 2006a). There are no randomized data establishing the role of interposition grafts. In retrospective, uncontrolled or non-randomized cohort studies, it is perhaps inevitable that surgeons will have employed grafting in their more complex cases, resulting in misleading conclusions regarding the value of the procedure. The tissues used include the following.

- Martius graft: labial fat and bulbocavernosus muscle passed subcutaneously to cover a vaginal repair; this is particularly appropriate to provide additional bulk in a colpocleisis, and in urethral and bladder neck fistulae may help to maintain competence of closure mechanisms by reducing scarring.

- Gracilis muscle passed either via the obturator foramen or subcutaneously (Hamlin and Nicholson 1969), or rectus abdominis muscle (Bruce et al 2000) may be used as above.
- Omental pedicle grafts (Kiricuta and Goldstein 1972, Turner-Warwick 1976) may be dissected from the greater curve of the stomach and rotated down into the pelvis on the right gastroepiploic artery; this can be used for any transperitoneal procedure, but has its greatest advantage in postradiation fistulae.
- Peritoneal flap graft (Jonas and Petri 1984) is an easier way of providing an additional layer at transperitoneal repair procedures, by taking a flap of peritoneum from any available surface, most usually the paravesical area.

Postoperative management

Fluid balance

Nursing care of patients who have undergone fistula repair is of critical importance, and obsessional postoperative management may do much to secure success. As a corollary, however, poor nursing may easily undermine what the surgeon has achieved. Strict fluid balance must be kept, and a daily fluid intake of at least 3 l and output of 100 ml/h should be maintained until the urine is clear of blood. Haematuria is more persistent following abdominal than vaginal procedures, and intravenous fluid is therefore likely to be required for longer in this situation.

Bladder drainage

Continuous bladder drainage in the postoperative period is crucial to success, and where failure occurs after a straightforward repair, it is almost always possible to identify a period during which free drainage was interrupted. Nursing staff should check catheters hourly throughout each day, to confirm free drainage and check output. Catheters should, of course, drain into a sterile closed drainage system with a non-return valve (Hilton 1987). In circumstances where supplies of sterile disposables are limited or where standards of nursing are poor, as in many developing countries, open drainage has been advocated with good success and low infection rates. Bladder irrigation and suction drainage are no longer recommended.

Views differ regarding the ideal type of catheter. The calibre must be sufficient to prevent blockage, although whether the suprapubic or urethral route is used is, to a large extent, a matter of individual preference. A urethral Foley catheter should probably be avoided following bladder neck fistulae, and either a suprapubic catheter or a non-balloon urethral catheter sutured in place would be preferred. The bladder should not be distended to insert a suprapubic catheter after a vaginal repair, although it could be inserted before surgery by the technique of cutting on to a sound. The author's usual practice is to use a 'belt and braces approach' of both urethral and suprapubic drainage initially, so that if one becomes blocked, free drainage is still maintained. The urethral catheter is removed first, and the suprapubic catheter retained and used to assess residual volume until the patient is voiding normally (Hilton 1987).

The duration of free drainage depends on the fistula type. Following repair of surgical fistulae, 12 days is adequate.

With obstetric fistulae, up to 21 days of drainage may be appropriate, although recent data suggest that this may not be necessary for less complicated cases (Nardos et al 2008). Following repair of radiation fistulae, 21–42 days of drainage may be appropriate. In any of these situations, it is wise to carry out dye testing (see above) prior to catheter removal if there is any doubt about the integrity of the repair. Where a persistent leak is identified, free drainage should be maintained for 6 weeks.

Bowel management

If patients are restricted to bed following urogenital fistula repair, a laxative should be administered to prevent excessive straining at stool. Traditionally, patients have been managed by nasogastric tube, by being kept nil by mouth until they are passing flatus, after abdominal repair of intestinovaginal fistulae; however, evidence that this approach is necessary is lacking. Once oral intake is allowed, or following vaginal repair of rectovaginal fistulae, a low-residue diet should be administered until at least the fifth postoperative day. Enemas and suppositories should be avoided, although a mild aperient such as dioctyl sodium (Docusate) is advised to ease initial bowel movements.

Subsequent management

On removal of catheters, most patients will feel the desire to void frequently since the bladder capacity will be functionally reduced having been relatively empty for so long. In any case, it is important that they do not become overdistended, and hourly voiding should be encouraged and fluid intake limited. It may also be necessary to wake them once or twice through the night for the same reason. After discharge from hospital, patients should be advised to gradually increase the period between voiding, aiming to be back to a normal pattern by 4 weeks after surgery. Tampons, pessaries, douching and penetrative sex should be avoided until 3 months after surgery.

Prognosis

Results

It is difficult to compare the results of treatment in different series since the lesions involved and the techniques of repair vary so greatly. Cure rates should be considered in terms of closure at first operation, and vary from 60% to 98% (Turner-Warwick et al 1967, Hamlin and Nicholson 1969, Chassar Moir 1973, Hudson et al 1975, Goodwin and Scardino 1979, Patil et al 1980, O'Connor 1980, Wein et al 1980, Elkins et al 1988, Lee et al 1988, World Health Organization 1989, Hilton 1995, Hilton and Ward 1998). In ideal circumstances, one might anticipate an 80% continence rate, 10% failures and, in the case of obstetric fistulae at least, 10% suffering from postfistula stress incontinence.

Of the 300 patients in the author's series managed in the UK, 25 (8.3%) healed without operation, 10 (3.3%) declined surgery, 12 (4.0%) were telephone referrals only and either healed spontaneously or were treated at their local hospital, five (1.7%) underwent primary urinary diversion, and four died from malignancy or the effects of radiation prior to

Table 57.5 Outcome of treatment in the author's series of urogenital fistulae treated in the north-east of England between 1987 and 2008

Aetiology		Surgical	Obstetric	Radiation/malignant	Miscellaneous	Total
Number		207	35	30	28	300
Healed spontaneously	<i>n</i>	18	4	0	3	25
	%	8.7	11.4	0	10.7	8.3

Primary repair procedure	<i>n</i>	180	28	16	20	244
	%	87.0	80.0	53.3	71.4	81.3
Closed at first operation	<i>n</i>	174	25	14	19	232
	%	96.7	89.3	87.5	95.0	95.1

treatment. Of the remaining 244 who have undergone repair surgery, 232 (95.1%) were closed at their first operation, although of these, 12 (5.2%) have some residual incontinence. More specifically, the rate of closure at first operation in the author's series is 97% in surgical cases, 95% in miscellaneous cases, 89% in obstetric cases and 88% in radiotherapy cases. Of the 130 fistulae following simple hysterectomy undergoing surgical treatment in Newcastle, 128 (98.5%) were cured at their first operation (Table 57.5).

Long-term outcome has rarely been considered. Dolan et al (2008) reported a median 4 year follow-up of women undergoing fistula repair in the UK. Despite their fistulae being anatomically closed, most women reported one or more urinary symptoms in the long term, although only one in eight found these symptoms significantly problematic. Frequency, nocturia, and stress or urge incontinence were the most common troublesome symptoms, and there was no obvious trend to improvement over time.

Of the largely obstetric fistulae reviewed from Nigeria by Hilton and Ward (1998), 81.2% were cured by the first operation and 97.7% were eventually successfully anatomically repaired, with only 0.6% undergoing urinary diversion. It is commonly assumed that follow-up of obstetric fistula patients after discharge from hospital is not feasible; however, two recent studies have found this not to be the case (Browning and Menber 2008, Nielsen et al 2009). Both studies found fistula closure to be associated with improvement in quality of life and reintegration into society. In the longer-term follow-up study of Browning and Menber (2008), although incontinence persisted in some patients, there was a tendency to further improvement over time.

A law of diminishing returns has been reported previously (Lawson 1978). Although repeat operations are certainly justified, the success rate decreases progressively with increasing numbers of previous unsuccessful procedures. In the series reported from Nigeria, although the cure rate at first operation was 81.7%, the success rate for those patients requiring two or more procedures fell to 65% (Hilton and Ward 1998). It cannot be overemphasized that the best prospect for cure is at the first operation, and there is no place

for the well-intentioned occasional fistula surgeon, be they gynaecologist or urologist.

Postfistula stress incontinence

Stress incontinence has long been recognized as a complication of vesicovaginal fistulae (Lawson 1967). It is most likely to occur in obstetric fistula patients when the injury involves the sphincter mechanism, particularly if there is tissue loss (Waldijk 1989, Browning 2006b), although it has also been reported in a large proportion of surgical fistulae involving the urethra or bladder neck (Hilton 1998). It affects at least 10% of all fistula patients, and its impact in terms of the patient's quality of life and mental health may be as great as that of the fistula itself (Browning et al 2007).

The extent of scarring in the area means that conventional approaches to bladder neck elevation may be technically difficult and of limited success. The use of a labial musculofat graft in the initial repair may reduce the likelihood of the complication (Waldijk 1994b), and a number of other techniques have been attempted (Hudson et al 1975, Waldijk 1994b). The implantation of an artificial urinary sphincter or neourethral reconstruction may be appropriate from a theoretical point of view (Hilton 1990), but the former would be prohibitively expensive, and both would be excessively morbid, for use in the developing world. Periurethral injections hold promise as a minimally invasive technique particularly appropriate in the situation of urethral insufficiency with a relatively fixed immobile urethra. Although initial success has been reported in postfistula stress incontinent patients (Hilton et al 1998), the long-term outcomes are disappointing.

Subsequent pregnancy

Although many patients with obstetric vesicovaginal fistula will experience amenorrhoea for 2 years or more after the causative pregnancy (Hilton and Ward 1998), where tissue loss is not great, hypothalamic function often returns to normal immediately after successful repair, and fertility may

be relatively normal. Kelly (1979) reported on 33 patients who became pregnant within 1 year of fistula repair, 12 of whom were delivered vaginally without damage to the repair. His criteria for attempting vaginal delivery were: that the fistula arose from a non-recurring cause (i.e. malpresentation as opposed to pelvic contraction), that an interposition graft had been utilized in the repair, and that the labour was conducted under skilled supervision in hospital (Kelly 1979). However, most other authorities have emphasized the need for caesarean section in any subsequent pregnancy (Lawson 1978). Most recently, in a study from Ethiopia, Browning (2009) described no recurrent fistulae, and 47 livebirths from 49 pregnancies delivered by a policy of elective caesarean section (in the rare cases where dates were certain) or emergency caesarean section at premature rupture of membranes or onset of labour.

Prevention

It has been estimated by the World Health Organization (WHO) that there are approximately 500,000 maternal deaths per year worldwide (World Health Organization 1989), and it is clear that the prevalence of obstetric fistulae and maternal mortality rates are closely related. Indeed, one might look on the vesicovaginal fistula patient as being the 'near-miss' maternal death. In recognition of this fact, WHO established, through their 'Safe Motherhood Initiative', a technical working group to investigate the problems of prevention and management of obstetric fistulae. The recommendations from that working group included the extension of antenatal and intrapartum care; the transfer of women in prolonged labour for delivery by skilled personnel; the identification of areas where fistulae are still prevalent, so that resources could be mobilized to deal with fistulae more effectively; and the creation of specialized centres for management, training and research, with a specific aim of treating existing cases within 5 years (World Health Organization 1989). One thousand years ago, Avicenna recognized the problems of early childbearing, saying: 'in cases where

women are married too young the physician should instruct the patient in the ways of prevent of pregnancy. In these patients the bulk of the fetus may cause a tear in the bladder which results in incontinence of urine which is incurable and remains until death' (Hilton 1995). Clearly, the achievement of WHO's aims and recommendations is critically dependent on major social change in areas of endemicity. Without improvement in the status of women, an extension of primary education, deferment of marriage and childbearing, improved nutritional status and contraceptive services, and skilled attendants in childbirth throughout the world, the problem of obstetric fistulae will remain with us well into the new millennium.

In the developed world, our concern must lie with the prevention and management of fistulae following gynaecological surgery. Primarily, we need to be aware of those factors increasing the likelihood of lower urinary tract injury during surgery, and must recognize the limits of our own, and perhaps more importantly our trainees', surgical skills. We should not expect staff in training to undertake surgery in cases where risk factors are known to be present without adequate supervision and support. We should be equally aware of the signs of injury in the postoperative period, and should have standard regimens for the management of patients with voiding difficulty in the postoperative period if bladder overdistension and risk of late damage is to be avoided. As indicated earlier, with advances in medical therapy for menorrhagia, and in minimally invasive surgery and techniques of endometrial resection/ablation, the need for hysterectomy is reducing considerably. However, hysterectomy will always be necessary for fibroids, endometriosis, sepsis and malignancy, and these carry the greatest risk of lower urinary tract injury. If these are the only cases on which our trainees can train, there is a danger that surgical skills, in general, may decline, in the same way that skills in vaginal breech delivery and rotational forceps delivery have declined with increasing use of caesarean section. Although the total number of fistulae seen in the UK is also reducing, the rate of urinary tract injury at hysterectomy seems, if anything, to be increasing.

KEY POINTS

1. In developing countries, over 90% of fistulae are of obstetric origin and are due to pressure necrosis from prolonged obstructed labour.
2. In the UK, approximately 70% of fistulae follow pelvic surgery, and 70% of these cases are associated with hysterectomy.
3. The characteristic presentation with continuous urinary leakage and reduced frequency and bladder sensation is not always present in patients with small fistulae, and a high index of suspicion must be maintained if the diagnosis is not to be missed. With intestinal fistulae, the history may be similarly misleading.
4. The upper urinary tracts should be assessed by intravenous or computed tomography urogram in all patients with urogenital fistulae.
5. The current best estimate is that urogenital fistula complicates one in 750 hysterectomies in the UK; this is rarely due to direct injury, and more often results from tissue ischaemia, adjacent sutures, haematoma or infection. Although poor surgical technique increases the risk, the mere fact of fistula development following hysterectomy does not imply negligence.
6. Where bladder damage is suspected or fistula is confirmed following surgery or childbirth, catheterization should be undertaken and continuous drainage maintained; spontaneous healing may occur up to 8 weeks after the initiating event.
7. The possibility of inflammatory bowel disease should always be considered in patients with intestinogenital fistula, even in the absence of specific bowel symptoms. Of the inflammatory causes, Crohn's disease is the most important. Ideally, surgical treatment should only be undertaken when the bowel pathology is quiescent.
8. Biopsy of the fistula edge or any unhealthy looking local tissue should be undertaken before embarking on repair of radiation, inflammatory or potentially infective fistulae.
9. Malnutrition, anaemia and infection should be treated before attempting surgical closure; this applies most particularly in patients with obstetric fistulae in the developing world.

10. Surgery for urogenital or intestinogenital fistulae should only be undertaken by surgeons with the appropriate training and experience, and with the versatility to undertake the most appropriate operation by the most appropriate route.
11. Layered closure with avoidance of tension on the suture lines, good haemostasis and obliteration of dead space are important technical points for successful closure.
12. Interposition grafting with pedicled fat or muscle may be a useful adjunct in fistula surgery, by providing an additional layer to the repair, filling dead space, bringing new blood supply and encouraging tissue mobility.
13. Successful anatomical closure of a urinary or intestinal fistula is not necessarily associated with restoration of complete functional normality. Incompetence of sphincter mechanisms may occur, with residual stress urinary incontinence, faecal soiling or incontinence of flatus. Although patients should be made aware that some residual symptoms may persist after fistula repair, for the majority, successful closure is associated with marked improvement in quality of life. For obstetric fistula patients, this is associated with reintegration into normal society.
14. Diversion of urinary or faecal stream should rarely be required as definitive measures for the management of obstetric or surgical fistulae, although they have a small but important place in the management of postradiotherapy fistulae.

Introduction

Urinary tract infections (UTIs) are a common cause of morbidity in women, affecting 50% of adult women at least once in their lives. In women aged 20–65 years, at least 20% will suffer an infection each year. Each year, approximately 5% of women will present to their general practitioners with dysuria and frequency (Hamilton-Miller 1994), and approximately half of these will have a UTI. It has been estimated that, on average, a case of uncomplicated acute cystitis results in 6.1 days of symptoms, 2.4 days of restriction of activities and 0.4 days in bed (Foxman and Frerichs 1985a). In women, the incidence of UTI increases with age and with the onset of sexual activity, and is highest amongst the elderly. In children under 1 year of age, the prevalence is higher in boys than girls, with a male:female ratio of 3:1–5:1. UTI in the neonate should be considered to be secondary to an underlying anatomical abnormality until proven otherwise (Kunin 1987).

The prevalence of UTI increases significantly with increasing age, and is higher in women than in men. In the elderly, the prevalence may be as high as 50%, especially if the woman is institutionalized (Boscia and Kaye 1987). This high prevalence in the elderly is thought to be secondary to cerebrovascular accidents, reduced mental and functional capacity, the use of bladder catheters and diabetes.

Approximately 25–30% of affected women will develop recurrent UTI that is not related to an underlying anatomical or functional abnormality of the urinary tract (Hooton 2001, Finer and Landau 2004).

This chapter will concentrate on UTI in the adult female and discuss strategies for treatment and prevention.

Terminology and Definitions

UTI is defined as inflammation of the urinary tract due to microbial invasion. There is considerable overlap in the clinical presentations of the various syndromes, including cystitis, pyelonephritis and urethritis. Complicated UTI is UTI associated with functional or anatomical abnormalities that increase the risk of serious complications or treatment failure, such as conditions which cause obstruction or relative stasis of urinary flow (Box 58.1).

Urine samples collected directly from the bladder, ureter or renal pelvis should be sterile. Urine passed through the urethra always contains some bacteria derived from the terminal urethra. Significant bacteriuria is defined by the culture of increased numbers of bacterial colony-forming units (CFUs). The absolute number needed to define significant bacteriuria depends on the sample type. The threshold of more than 10^5 CFU/ml has been a standard for the definition of significant bacteriuria using carefully collected midstream urine (MSU) since the 1950s (Kass 1956). A significant proportion of patients with UTI will have less than 10^5 CFU/ml (Johnson and Stamm 1987, 1989). Therefore, current recommendations (Warren et al 1999) suggest more than 10^3 CFU/ml for a diagnosis of cystitis, and more than 10^4 CFU/ml for a diagnosis of pyelonephritis. An important consideration with these diagnostic criteria is that they rely on careful collection of the MSU. This requires that care is taken in the instruction and support that patients are given to collect these samples. Bacteriuria is common in association with any long-term catheter and is not in itself an indication for treatment of UTI.

Box 58.1 Conditions associated with a complicated UTI**Obstruction/structural**

- Presence of stones, catheters, stents or abnormalities, nephrostomy tubes
- Urinary tract malignancy
- Diverticuli
- Fistula
- Ileal conduits/urinary diversions
- Coexisting pelvic malignancy or inflammatory bowel conditions

Functional abnormality

- Neurogenic bladder
- Anticholinergic drugs (leading to incomplete bladder emptying)

Miscellaneous

- Diabetes mellitus
- Pregnancy
- Renal failure
- Immunosuppression
- Hospital-acquired/resistant infections

Asymptomatic bacteriuria is defined as the presence of more than 10^5 CFU/ml in two MSU samples in the absence of symptoms (Zhanel et al 1990). Cystitis is an inflammation of the bladder which may be due to infection or a variety of other causes. Urethritis is inflammation of the urethra and may be a consequence of a wide range of causes including UTI, sexually transmitted diseases such as chlamydia, vaginitis, trauma and allergy. Bacterial pyelonephritis is infection of the renal pelvises which may be acute or chronic.

Microbiology of Urinary Tract Infection

The majority of UTIs are caused by facultative bacteria and, occasionally, by fungi and viruses. *Escherichia coli* accounts for up to 70% of community-acquired infections (Grüneberg 1994), with the remainder predominantly caused by *Staphylococcus saprophyticus* and a variety of Gram-negative rods within the Enterobacteriaceae. In hospital-acquired infections, approximately 50% are caused by *E. coli*, 15% by *Enterococcus* spp. and the remainder by members of the Enterobacteriaceae, *Pseudomonas* spp., *Staphylococcus* spp. and yeasts (Bryan and Reynolds 1984). Hospital-acquired UTIs are frequently associated with iatrogenic risk factors such as instrumentation, and also with patient comorbidities. Antibiotic resistance is also much more likely to complicate hospital-acquired UTI.

Pathogenesis

There are host, iatrogenic and bacterial factors that contribute to the pathogenesis of UTI. Foreign bodies such as urinary catheters are major risk factors for infection through mechanisms that include trauma, compromise of local immunity, and by providing protected niche(s) for microbial proliferation and surfaces for biofilm production.

Bacterial virulence factors

The ability of bacteria to adhere to uroepithelial cells is a prerequisite for infection to occur, and reduces the chance of the bacteria being cleared from the urinary tract during voiding. There are various adherence factors, called 'adhesins'; *E. coli* possess surface organelles called 'pili' that act as adhesins. These adhesins attach to complementary structures on the uroepithelial cell wall, and act not only to promote infection but also to help promote growth and toxin production (Zafriri et al 1987). There are many different types of adhesins, such as type 4 pili, outer membrane proteins, curli, filamentous haemagglutinins and adhesive pili. Other virulence factors that may facilitate infection are specific to each pathogen. These include the surface antigens on *E. coli* and haemolysins that are produced to help degrade cells, and aerobactins that enhance iron uptake which encourages *E. coli* growth.

Much of our understanding of UTI comes from the study of uropathogenic *E. coli* (UPEC). The type of pili of the different strains of UPEC may determine the site of disease in the urinary tract as they have specific cell affinity (Gunther et al 2002). The virulence of UPEC has been attributed mainly to the presence of type 1 fimbriae, a mannose-binding adhesion protein called 'FimH' (Abraham et al 1988). Another pathogenic mechanism is the development of intracellular UPEC pods which act as a reservoir for infection (Anderson et al 2003). These pods contain bacteria that are encased in a polysaccharide matrix and protected by a uroplakin coating which help to evade host defence mechanisms and antimicrobials. This initiates the invasion into cells to develop intracellular bacterial communities. It is this reservoir that can serve as a source of bacteria that may reinstate infection (Figure 58.1)

Host factors

Regular voiding flushes the urinary tract of pathogens and the acidity of urine inhibits bacterial growth. A healthy vaginal flora is thought to be essential in reducing infection. This flora is predominantly lactobacilli and this maintains an acidic pH in the vagina. Lactobacilli and uromucoid in the urine are thought to interfere with bacterial adherence and colonization. It is also thought that the composition of the flora is important as it provides a continuous microbial stimulus to the host immune system, such that it is primed to respond to pathogens. In women with recurrent UTI, the flora has reduced lactobacillus composition (Kirjavainen et al 2009). The glycosaminoglycan layer of the bladder also serves as a protective layer preventing bacterial adherence.

Factors that increase the risk of infection include:

- impaired bladder emptying which can occur with neurogenic disorders such as diabetes, multiple sclerosis, cerebrovascular events and anatomical abnormalities. Anticholinergic drugs may also impair bladder emptying;
- instrumentation of the urinary tract which may traumatize the urethra;
- foreign bodies such as catheters and stones increase the risk of infection as they are a focus for infection;

Figure 58.1 Intracellular bacterial communities extend like pods into the bladder lumen. Infected bladders were bisected, fixed and visualized by either scanning electron microscopy (SEM) or light microscopy [haematoxylin and eosin (H&E) staining]. (A–C) SEM images of a pod on the surface of a C3H/HeJ mouse bladder infected with UT189 for 24 h show large intracellular communities of bacteria inside pods. Scale bars: 50 μm (A), 5 μm (B), 0.5 μm (C). (D) SEM revealed no pods in C3H/HeJ bladders infected with MG1655. Scale bar: 50 μm . (E) H&E-stained sections of UT189-infected C3H/HeJ mouse bladders show a bacterial factory 6 h after inoculation (top panel) and a pod 24 h after inoculation (bottom panel). Bacteria in the pod were densely packed, shorter and completely filled the host cell. Video microscopy has shown that bacterial factories mature into pods. Scale bars: 20 μm . (F) Pods were evident in wild-type C3H/HeN bladders infected with UT189. Scale bar: 50 μm . (G) Confocal Z-section series from whole-mounted bladder infected with UT189 expressing green fluorescent protein from the plasmid pcomGFP and stained with antibody to uroplakin (primary antibody) and tetramethyl rhodamine isothiocyanate-labelled secondary antibody, showing uroplakin coating the surface of pods. The series depicts the luminal surface on the left and progresses through the epithelium toward the right. Optical section thickness: 1 μm . All images are representative of the entire sample surface and are from bladders harvested 24 h after inoculation, unless otherwise indicated.

- pelvic tumours and inflammatory bowel disorders may invade the bladder directly and also affect bladder emptying;
- glycosuria that occurs in diabetes mellitus is a potent culture medium for bacterial growth;
- genetic factors have been postulated to increase the risk of recurrent infection. Women with recurrent infection are more likely to be non-secretors of histo-blood group antigens, and *E. coli* is found to adhere better to uroepithelial cells of non-secretors than secretors (Lomberg et al 1986, Sheinfeld et al 1989). Further evidence for a genetic susceptibility is that female relatives of women with recurrent UTI are more likely to suffer from UTI as an adult (Hopkins et al 1999);
- in menopausal women, the lack of oestrogen reduces lactobacillus growth and, with the rise in vaginal pH, leads to a predisposition to growth of enterobacteria (Cardozo 1996); and
- sexual intercourse and contraception are strongly associated with the onset of UTI (Hooton et al 1996, Foxman et al 1997). Sexual intercourse not only results in trauma and disruption to the uroepithelial cells, but may also introduce rectal and vaginal bacteria into the urethra. In a woman who has had sex in the previous 48 h, the odds ratio for a UTI is increased 60 times over a woman who has not (Nicolle et al 1982). The use of spermicides with diaphragms alters vaginal flora, increases vaginal pH and decreases lactobacilli concentration, promoting colonization with *E. coli*.

In addition to all these factors, there is a well-developed and effective innate and adaptive host response to bacterial invasion. The mucosal lining of the urinary tract has a number of immune surveillance molecules that function to recognize invading pathogens. The best characterized of these is the Toll-like receptor (TLR) family (Samuelsson et al 2004, Zhang et al 2004, Anderson-Nissen et al 2007). These receptors function to initiate appropriate host immune defences when triggered by a pathogen. There are 11 TLRs; TLR4 is the best characterized and is present on the epithelial cells of the bladder and kidney, and promotes cytokine and chemokine responses to Gram-negative pathogens. This TLR4 response can still occur even once intracellular bacterial invasion has occurred. The importance of host-mediated immunity can be seen in women with recurrent UTI. A study comparing vaginal, urine and blood samples from 22 women with recurrent UTI and 17 controls showed an aberrant immune response. Women with recurrent UTI had defective T-cell activation and a lower concentration of tissue-repair-associated vascular endothelial growth factor (Kirjavainen et al 2009).

Natural History

In children up to 1 year of age, 1.1% of girls and 1.2% of boys may suffer a symptomatic UTI. In school-age children, a UTI has been reported in 8% of girls and 2% of boys (Hansson et al 1997). The sequelae of UTI in neonates and young children include pyelonephritis and renal scarring, especially if infection occurred before 5 years of age. Vesico-

ureteric reflux is a significant aetiological factor in the occurrence of UTI in the young.

In young women, UTI can result in asymptomatic bacteriuria, cystitis and pyelonephritis. These do not usually affect renal function, except in the elderly where bacteriuria has been associated with a decrease in glomerular filtration rate. In pregnancy, UTIs have been associated with an increased risk of prematurity, perinatal mortality and perinatal complications (Maclean 2000). The incidence of asymptomatic bacteriuria is similar to non-pregnant women (4–7%) (Patterson and Andriole 1997); however, in pregnancy the risk of developing a symptomatic UTI is much higher, and 10–30% of women with asymptomatic bacteriuria develop pyelonephritis.

Presentation

A UTI may present either as an asymptomatic bacteriuria, acute cystitis or, more seriously, as acute pyelonephritis, bacteraemia and renal failure. The classic symptoms of acute cystitis include dysuria, frequency, urgency and suprapubic pain. If the upper urinary tract is involved, haematuria, loin pain, renal angle tenderness and fever may also occur. In children and the elderly, the classic clinical features of a UTI may not be present. In young children, clinical features of a UTI may be failure to thrive or a non-specific abdominal pain. In the elderly, UTIs often present as confusion and general malaise.

Physical Signs

In cases of acute cystitis or urethritis, there is often suprapubic tenderness and, occasionally, fever. The clinical presentation of acute pyelonephritis is often much more florid, with the patient often looking unwell with pyrexia and tachycardia. There is usually loin tenderness and, if severe, features of septicaemia may be present. In young children and the elderly, as with symptoms, clinical signs may be non-specific and atypical in nature.

Other associated physical signs which may point to the aetiology are a sensory neuropathy or evidence of a spinal cord lesion in cases of a UTI secondary to a neuropathic bladder.

Management

History and examination

In many women, infection can be diagnosed on the basis of history and clinical examination alone. A history should be taken to identify any predisposing features, such as recent UTI, recent urinary tract operations, recent sexual intercourse and the use of the contraceptive diaphragm and condom. Poor bladder emptying secondary to neurological disorders or the use of anticholinergic therapy, pregnancy, the presence of pelvic tumours and diabetes mellitus may also predispose to infection.

Clinical examination should include a general systemic examination, especially if the patient is pyrexial. Examination of the renal angles is required to elicit signs of

pyelonephritis. If a neuropathy is suspected, a neurological examination of the S2–4 nerve roots should be performed, assessing for sensation around the buttocks. A gynaecological examination should be performed to exclude residual urine, a pelvic mass or pregnancy. Differential diagnoses that should be considered include detrusor overactivity, cystitis, bladder stones or tumours, ovarian torsion or cysts, ectopic pregnancy and miscarriage.

Investigations

Investigations should be aimed to help select appropriate treatment and to exclude any underlying cause which may predispose to recurrence (Arnold 2000).

Urinalysis

Freshly voided urine may be cloudy if it contains large numbers of cells (e.g. bacteria, red or white blood cells). Urine which has been allowed to stand may also become cloudy as a result of the formation of crystals as the urine cools.

Commercial stick tests are available for detection of various urinary components. The tests which are most useful are those for the detection of white blood cell leukocyte esterase and nitrites (formed from the conversion of urinary nitrate by bacteria). A clear freshly voided urine with negative nitrite and leukocyte tests indicates that UTI is unlikely (a high negative predictive value). The stick tests are not reliable to exclude asymptomatic bacteriuria when the patient has recently received antibiotics, in the immunocompromised, if there are delays in testing the urine, or if the number of bacteria is less than 10^5 CFU/ml (Stevens 1989). Patients with suspected UTI should be treated empirically and promptly, even with negative stick test results. It is imperative that urine culture is performed in pregnancy, in the immunocompromised, in those with complicated infections, and where previous empirical therapy has failed.

Urine microscopy and culture

Urine culture has traditionally been the gold standard for the diagnosis of UTI. An MSU sample requires that the vulva is separated, the periurethral area cleaned with water, and a sample collected midstream. The quantitative criteria for diagnosis of bacteruria or infection require that the sample is collected carefully. If a catheter is in place, the sample should be taken by syringe aspiration or via a drainage port. Samples should ideally be cultured within 4 h. Urine samples can be stored overnight at 4°C. Borate can be used as a preservative; however, if used, it is important that the container is filled to the correct level to ensure that the borate concentration is within the correct range to act as a preservative rather than a disinfectant.

There are a variety of methods in current use for urine microscopy, including automated image analysers, flow cytometry and manual light microscopy. It is important to be aware of normal ranges for the technology used, and also the relevant test performance measures such as positive and negative predictive values. An increase in the numbers of bacteria and white blood cells above the normal range has a high positive predictive value for UTI. Urine

culture has the advantage of allowing detection of the organism and appropriate antibiotic sensitivities. Urine culture methods are designed to detect the bacterial species most frequently associated with UTI, and may not culture fastidious bacteria or those that grow slowly such as *Mycobacterium tuberculosis*. If tuberculosis is suspected, at least three early-morning urine specimens should be sent for culture using appropriate methods. Catheter urine samples frequently grow mixtures of bacteria, as do contaminated samples or following microbial proliferation following delays in sample transport.

Imaging studies

The majority of women with uncomplicated UTIs can be managed on the basis of a history, examination and basic laboratory investigations such as urinalysis and culture. In these situations, there should be a good response to antibiotics. Radiological evaluation may be useful to help direct treatment in those with complicated UTIs, such as those in whom there are features suggestive of obstruction, a fever that does not settle despite 48 h of intravenous therapy, or an uncommon infective agent. Imaging modalities that are available include ultrasound, intravenous urography, computed tomography (CT) and magnetic resonance imaging (MRI). Each has potential advantages and disadvantages to consider.

Intravenous urography

Intravenous urography has largely been superseded by ultrasound and isotope studies which do not utilize high-dose radiation and are free of the risk of allergy. It does, however, have the advantage that it delineates the anatomical relationships of the ureter, and can detect the level and severity of obstructive lesions. It is particularly indicated in the investigation of unexplained haematuria. It does, however, have lower sensitivity for detecting emphysema and perinephric abscesses compared with CT imaging.

Ultrasound

Ultrasound has the advantage of being easily accessible, cost-effective and free of radiation, and therefore can be used in childbearing women. It can be used to delineate the contours of the kidneys, and assess obstruction and bladder emptying. However, the use of ultrasound is limited in the visualization of the midportion of the urethra, which is often the site of obstructive lesions or stones. It may also be limited in patients of high body mass index. Ultrasound is useful for the detection of parenchymal tumours, but it has low specificity for the detection of urothelial tumours of the renal pelvis or urinary tract.

Ultrasound can also measure postvoid residual volume which may be useful if poor bladder emptying and a high residual urine is thought to be predisposing to infection.

Plain abdominal radiograph

Plain abdominal radiography can be used to supplement an ultrasound to detect stones or foreign bodies. If stones are present, 90% will be visualized as they contain calcium or cystine and so are radio-opaque. Calcification in lymph nodes or renal tumours may also be seen. In combination with ultrasound, it has been shown to be superior to an

intravenous urogram and incurs less radiation exposure (Lewis-Jones et al 1989, Spencer et al 1990).

Micturating cystogram

A micturating cystogram is useful in the detection of vesico-ureteric reflux, particularly in children, which often results in renal damage. This investigation should also be considered in women with recurrent upper tract infection or evidence of upper tract damage.

Nuclear medicine scanning

Nuclear medicine scans are generally only of use in complicated infections. They can be used to detect obstruction and also to evaluate differential function within each kidney.

The DMSA (dimercaptosuccinate) nucleotide is retained in the renal tubules and therefore this scan delineates renal anatomy and function. In patients with acute pyelonephritis, the affected area or scarring may be seen, along with any deterioration in proximal function. It should be considered in women with severe or unresolving pyelonephritis. In children under 5 years of age, it is more sensitive than ultrasound and intravenous urography in detecting renal scars (Mansour et al 1987). If obstruction is suspected, a DTPA (diethylenetriamine penta-acetic acid) or MAG3 (mercapto-acetyl triglycerine) scan is useful, as obstruction will result in delayed washout of the isotope from the renal pelvis. It will also allow calculation of the glomerular filtration rate and assessment of the contribution of each kidney to total renal function. MAG3 scans are also useful in delineating areas of reduced uptake and renal scars.

Computed tomography

In the majority of cases, ultrasound and intravenous urography are sufficient to reach a diagnosis; however, CT scanning is a useful adjunctive test where ultrasound and intravenous urography fail to make a diagnosis. In many units, CT imaging is now readily available and used for its increased sensitivity. It also allows a more global assessment of the pelvis. CT allows detailed anatomical demonstration of the kidney, intrarenal collecting system, ureter and bladder (Silverman et al 2009). It can thus be used for the investigation of haematuria.

CT can be used without contrast; however, the use of contrast does allow better anatomical detail and may give functional information. Contrast is usually injected into the collecting system 2–3 min after injection, and imaging can be performed at different stages of contrast enhancement to delineate areas of low or abnormal attenuation, such as seen with damaged parenchyma (Kawashima et al 1997).

In acute pyelonephritis, CT can be used to delineate focal or diffuse changes in the renal architecture and define the extent of hydronephrosis (Talner et al 1994). Spiral CT scan images, which are very much faster, can also detect ureteric stones or abscesses.

Magnetic resonance imaging

MRI has the advantage over CT that it does not use ionizing radiation or iodinated contrast. However, it is generally more expensive, less accessible and may be less well tolerated by patients and sensitive to motion artefact. It is also less sensitive for detecting renal calculi (Silverman et al 2009).

Blood tests

If deterioration of renal function is suspected, plasma creatinine and urea estimation should be performed. If diabetes is suspected, a fasting glucose test or glucose tolerance test should be performed.

Cystoscopy

Cystoscopy is rarely useful in the diagnosis of uncomplicated infection, but it is indicated in all cases of haematuria and may be considered in women with symptoms of recurrent cystitis or infection. It can be used to identify any predisposing factors for infection, such as a bladder tumour or stone.

Treatment

There are three principles in the management of infection. General supportive measures relieve symptoms and may help to eradicate infection. Antimicrobial therapy should be instituted appropriately, and if an underlying cause is found, such as obstruction, this should be treated. Finally, prevention of further infection will help to reduce recurrence.

General measures

Generally, patients are advised to maintain a high fluid intake of at least 2 l/day and to void regularly to ensure adequate bladder emptying. However, there is not much evidence that this practice improves outcomes over and above appropriate antibiotic therapy. If the patient is septicaemic, more intensive supportive measures and monitoring are required. Intravenous fluids, vasoactive drugs and treatment of the septicaemia should be considered.

Antimicrobial therapy

The aim of antimicrobial therapy is to eradicate pathogenic organisms with minimal local and systemic side-effects. A suitable antimicrobial agent should reach a suprainhibitory concentration in urine and have activity against the range of common causative agents of UTI. An ideal antibiotic would have a low potential to select for bacterial resistance and to give rise to side-effects, be inexpensive and easily administered. Selection of antibiotics for empirical treatment should take account of local resistance patterns, which may vary geographically and are also dependent on whether the infection is hospital or community acquired. Side-effects include anaphylaxis, skin rashes, gastrointestinal disturbances, fungal infection and *Clostridium difficile* colitis (particularly in the elderly). Multiresistant *E. coli* is becoming more commonly recognized as a cause of community-acquired as well as hospital-acquired infection, making the requirement to take account of local antibiotic resistance information increasingly important when designing treatment algorithms.

Many antibiotics administered systemically reach much higher concentrations in urine than in serum. These include β -lactams, aminoglycosides, fluoroquinolones and trimethoprim, so large doses of these agents are rarely required. Amoxycillin resistance is now so common in laboratory

isolates in the UK that it is best avoided in the empirical treatment of UTI, and in some areas, trimethoprim resistance is reaching similar levels. The true level of antibiotic resistance amongst agents of community infection is not known. The levels of resistance in laboratory isolates from patients in the community may be an overestimate because of biases in the way in which laboratories are used. For example, samples may only be sent to the laboratory when patients return to a doctor after failure of empirical treatment. Estimates of the levels of antibiotic resistance for hospital infections may be more accurate because of the relative ease of use of the laboratory. Alternatives to amoxicillin or trimethoprim for oral use include nalidixic acid, penicillin/enzyme inhibitor combinations (such as amoxicillin with clavulanate), nitrofurantoin, oral cephalosporins and quinolones. The British National Formulary gives good advice on antibiotic selection and treatment durations for specific clinical scenarios. The duration of therapy has come under some debate with a move to shorter regimes to increase compliance, as these will have less effect on the faecal and vaginal flora and reduce the risk of resistant strains. Three-day regimes are as effective as 5- and 7-day regimes for those with uncomplicated UTI (Norrby 1990). Ideally, protocols should be developed with local microbiologists and/or infectious disease specialists that take account of local resistance information. Additional information on the use of antibiotics is provided in the section dealing with specific clinical presentations.

Prevention

For many women with recurrent infection, suggested preventive measures include maintaining a high fluid intake, instructions on perineal hygiene such that the perineum is wiped from front to back after defaecation and micturition (thus reducing the risk of faecal contamination of the urethra), and the avoidance of bubble baths, vaginal deodorants and specific underwear. The benefits of these practices are unclear and they have not been shown to reduce the frequency of infections in case-control studies (Foxman and Frerichs 1985b, Remis et al 1987).

There is, however, a strong association between sexual behaviour and contraceptive use (Foxman and Chi 1990). If sexual intercourse is a precipitating factor, postcoital treatment and voiding are recommended. In women using spermicides and diaphragms for contraception, alternative methods may be recommended.

The beneficial effects of cranberry juice are receiving increasing attention as a simple remedy that reduces the incidence of recurrent infection; however, most studies have been relatively small and inconclusive. There are two postulated mechanisms of action: competitive inhibition of the *E. coli* fimbrial subunit to the uroepithelial cells, or prevention of the expression of the normal fimbrial subunits (Patel and Daniels 2000). In a randomized double-blind trial to determine the effect of cranberry juice on bacteriuria and pyuria in 153 elderly women, there was reduced frequency of bacteriuria (15% vs 28%) with daily ingestion of 300 ml of cranberry juice (Avorn et al 1994). There was a decrease in the incidence of symptomatic UTI but this did not reach statistical significance; however, antibiotic use decreased by approximately 50% in the group who drank cranberry juice.

The Cochrane analysis of cranberries for prevention of UTI found that the studies assessed were flawed as the amount and type of cranberries given differed, and there was only weak evidence to support the use of cranberry juice for prevention (Jepson et al 2004).

In postmenopausal women, there is increased susceptibility to infection secondary to the changes in the vaginal flora and the uroepithelium secondary to oestrogen deficiency. There are few randomized trials of hormone replacement therapy in the prevention of UTI. In a double-blind, placebo-controlled trial of oestriol cream for the treatment of recurrent infection in 93 women, Raz and Stamm (1993) found that those on topical oestriol had a lower incidence of UTI (0.5 vs 5.9 episodes/patient-year). The decrease in UTI was seen together with a decrease in vaginal pH and recolonization with lactobacilli. In a later study by Cardozo et al (1998), daily use of oestriol cream was found to be superior to placebo in the treatment of recurrent UTI.

The recent Cochrane review (Perrotta et al 2008) of oestrogen use in postmenopausal women with recurrent UTI reviewed nine studies which included 3345 women. The data were difficult to summarize as studies were heterogeneous and used different application methods and doses. Pooled data from four studies showed that oral oestrogens did not reduce UTI compared with placebo. There were two small relevant studies comparing vaginal oestrogens which showed a reduction in UTI.

Low-dose prophylactic antibiotics can be considered if the frequency of attacks is two or more per 6 months or three or more over 12 months (Nicolle and Ronald 1987, Stamm and Hooton 1993). The aim of treatment is to eradicate urinary bacteria without affecting the healthy flora of the bowel and vagina, or causing the development of resistant strains. The usual suppressive dose is one-quarter to one-third of the antimicrobial dose required to treat an acute infection. This is usually prescribed at night to maintain a high antimicrobial concentration for as long as possible. The antibiotics of choice are trimethoprim, trimethoprim and sulphamethoxazole, nitrofurantoin, nalidixic acid and cephalexin (Harding et al 1982). In patients with neuro-pathic bladders, long-term indwelling catheters or ileal conduits who are at increased risk of recurrent infection, it is not advisable to begin long-term prophylaxis as this increases the risk of resistance and antimicrobial side-effects. In these cases, the patient should be advised to seek early treatment when a UTI is suspected.

Future approaches to treatment

The increasing problem of antimicrobial resistance and the lack of efficacy of conventional therapy in recurrent infection has led to new strategies to reduce bacterial penetration and alter the host innate or adaptive immunity.

There is much interest in the use of lactobacillus-containing probiotics for preventing recurrent infection. Probiotics are 'live micro-organisms' and the rationale for their use is that they restore the commensal flora of the genitourinary tract which inhibits colonization with uropathogens. Four randomized trials (Reid et al 1992, 1995, Baerheim et al 1994, Kontiokari et al 2001) have studied lactobacilli for the prevention of recurrent UTI; however, only one reported a reduction in episodes of recurrent UTI.

compared with the year prior to the study (Reid et al 1995). There are also concerns regarding the stability of probiotics and strain-specific effects.

The identification of various *E. coli* adhesins, including the type I and P fimbriae, has stimulated the search for vaccines against the development of UTI. Animal studies have shown that vaccination with antibodies to the FimH adhesin, which mediates binding to the bladder mucosa, reduces bacterial binding, bacteriuria and pyuria (Langemann et al 2000).

As the host immune response may determine susceptibility to infection, modulators of the immune system have been proposed as adjuvants to help boost the normal immunological mechanisms to vaccines (Ishii and Akira 2007, Parker et al 2007). Data from animal studies have shown a greater antigen-specific immune response and a reduced bacterial load when immunomodulators have been used (Bishop et al 2007, Huleatt et al 2007).

The clinical application and efficacy of these new strategies for treatment are still unclear; however, if found to be useful, they may act in combination or instead of antimicrobials to decrease recurrent infection and increase treatment efficacy.

Specific Clinical Situations

Asymptomatic bacteriuria

Asymptomatic bacteriuria is defined as the presence of increased numbers of bacterial CFUs in a urine sample in the absence of clinical signs or symptoms of UTI. In a carefully collected MSU sample, this number is more than 10^5 CFU/ml. If left untreated, 60–80% of patients will spontaneously clear the infection without long-term sequelae. However, there are several situations where treatment is advisable. In obstetric and gynaecological practice, these situations include pregnancy and urogenital surgery.

There has been much debate on the benefits and cost-effectiveness of screening pregnant women for asymptomatic bacteriuria. The prevalence of asymptomatic bacteriuria has been reported to range from 2% to 13% (Norden and Kass 1968). There is an association with premature birth and low birth weight (Andriole and Patterson 1991), as well as an increased risk of developing pyelonephritis. In a study of 5000 antenatal patients, it was reported that in women with asymptomatic bacteriuria in pregnancy, 36% progressed to acute pyelonephritis if untreated compared with 5% if treated (Little 1965). Current recommendations in the UK (National Institute for Health and Clinical Excellence 2008) support the screening of pregnant women for bacteriuria at the time of booking by urine culture, because treatment with antibiotics reduces the risk of pyelonephritis. Antibiotic choices should be based on the culture result and should take account of the safety profile of the selected agent in pregnancy. Tests for urinary nitrite and leukocyte esterase are unreliable for the diagnosis of asymptomatic bacteriuria (Tincello and Richmond 1998).

Recurrent infection

Up to 20% of women with acute cystitis develop recurrent UTI which is defined as three or more laboratory-confirmed

infections per year. These occur due to either reinfection or a relapse of persistent infection. Risk factors such as atrophic vaginitis should be looked for and treated. Maintaining a good urine output is advisable to promote voiding and avoid urinary stasis. Prophylactic use of trimethoprim, nitrofurantoin or norfloxacin therapy may reduce the risk of recurrent attacks but may also select for antibiotic resistance. Cranberry juice may reduce the risk of recurrent UTI without the risk of antibiotic resistance (Kontikari et al 2001).

Postcoital prophylaxis with a single dose of an antibiotic can be used if infection is related to intercourse. Alternatively, patients can be given antibiotics to use when symptoms occur, or daily prophylaxis with nitrofurantoin, trimethoprim, norfloxacin or cephalexin. A 6-month trial of prophylaxis is usually recommended, with the patient observed to see if infection recurs once the regime is discontinued. However, recurrence seems to occur and a longer period of prophylaxis is now advocated for at least 2 years. Antimicrobials such as trimethoprim have been effective and well tolerated for up to 5 years (Nicolle and Ronald 1987, Nicolle et al 1988).

Acute pyelonephritis

Prompt antimicrobial treatment reduces the risk of serious adverse outcomes, so treatment should be commenced as soon as a diagnosis of urosepsis is considered (clinical signs and symptoms of UTI such as dysuria or loin pain in association with systemic signs of infection such as fever, rigors, hypotension, tachypnoea and tachycardia) and prior to the results of urine culture. Potential complications of pyelonephritis include Gram-negative bacteraemia, endotoxic shock and disseminated intravascular coagulation. In general, acute pyelonephritis resolves without long-term renal damage in the majority of women. However, in the presence of obstruction, such as with stones, infection may result in papillary necrosis, renal or perinephric abscess, or xantho-granulomatous pyelonephritis (Cattell 1998). Treatment consists of aggressive supportive treatment including rehydration and intravascular volume expansion.

Drugs of choice for parenteral therapy include cephalosporins, fluoroquinolones or an aminoglycoside. After the culture results are available, treatment may be changed to the appropriate antibiotic if necessary in consultation with a microbiologist or infectious disease specialist. The duration of treatment is usually 10–14 days (Bailey 1998, Cattell 1998).

Imaging of the renal tract is not usually necessary unless there has been no response to antibiotics or if there is a strong clinical suspicion of renal tract obstruction. Intravenous urography will be normal in 75% of cases of uncomplicated acute pyelonephritis (Fraser et al 1995), as well as renal ultrasound. CT imaging is usually normal unless infection is severe, when changes include renal enlargement, focal swelling and parenchymal attenuation.

Catheter-associated infection

Urethral catheterization is a major risk factor for UTI and local trauma, so should not be undertaken lightly. Those who carry out urinary tract catheterization should have

received appropriate training in technique and catheter type (Carter et al 1990). A UTI is reported to occur in approximately one-third of patients catheterized in hospital (Hayley et al 1985). The risk of a UTI after an in-out catheter is 1–2% (Turck et al 1962), but the risk is higher in pregnancy, with a high bladder residual and in the immunocompromised. Basic measures such as the use of a closed-drainage system and gravity-dependent drainage of urine decrease the risk of UTI, and a policy of expediting catheter removal as soon as clinically appropriate should be practised.

Long-term urinary catheters become colonized with bacteria, and UTI is a frequent complication. The underlying cause is the development of a pathogenic biofilm on the surface of an indwelling catheter. The rate of bacteriuria is 3–10%/day and approaches 100% in those with long-term catheters (Warren et al 1982, Saint et al 2002). Inhibiting biofilm formation is one mechanism to reduce UTI, and urinary catheters have been modified to promote this. Impregnation of catheters with antimicrobial agents such as silver have been shown to delay or reduce the onset of bacteriuria; however, there is the possibility of future resistance to silver (Brosnahan et al 2004). Treatment may be required when the patient develops systemic signs or symptoms of infection. Antibiotic treatment choice is best based on culture results.

Urinary tract tuberculosis

Urinary tract tuberculosis is usually caused by *M. tuberculosis* or, more rarely, *M. bovis* or *M. africanum*. Bloodborne spread occurs from the initial primary site, usually the lung but occasionally the gut. This form of tuberculosis tends to affect young adults and presents as a miliary tuberculosis or a nodular or cavitating tuberculosis affecting one kidney. Three early-morning specimens should be sent for Lowenstein-Jensen culture for acid-fast bacilli, as routine culture is sterile and usually reveals pyuria and haematuria alone. Renal function is usually normal unless there is widespread parenchymal damage. Therefore, urea and creatinine levels should be assessed in all patients, and renal imaging should be undertaken to reveal the extent of the disease. Intravenous urography and cystoscopy should also be performed to assess the presence of urethral strictures, pyocalyx, pyonephrosis or a non-functioning kidney. Characteristic appearances on intravenous urography and ultrasound include hydronephrosis and/or a small bladder. Bladder biopsies may be taken which culture more readily than urine; this can take up to 8 weeks until con-

sidered truly negative. A chest radiograph should also be performed.

After diagnosis, antituberculous therapy should be commenced. This consists of a four-drug treatment regime usually with isoniazid, rifampacin, ethambutol and pyrazinamide, modified to two drugs when the sensitivities of the tubercle bacilli are known. In total, if rifampacin is used, treatment should continue for 9 months.

Contact tracing should be performed as tuberculosis is a notifiable communicable disease and contacts need prophylaxis.

Urolithiasis

In the presence of a stone, a UTI must be treated and the urinary tract drained before removal of the stone. If a pyonephrosis or perirenal abscess is complicating the stone, immediate drainage using percutaneous nephrostomy is required. A xanthogranulomatous pyelonephritis is a rare complication of a UTI in the presence of a stone. This usually presents with loin pain, intermittent fever, anaemia and malaise. A palpable unilateral renal mass is usually present and, as well as a positive urine culture, liver function may be deranged. These cases are often resistant to antibiotics and a nephrectomy will be required.

Histologically, the affected kidney will show diffuse replacement of the renal parenchyma with lipid-filled macrophages, neutrophils, plasma cells and necrotic debris.

Conclusions

UTIs are the most common type of infection in women and a significant cause of distress and morbidity. The aetiology is multifactorial, and treatment strategies are based on identifying any predisposing causes and eradicating pathogenic organisms adequately to prevent recurrence of infection and long-term sequelae.

The management of women presenting with symptoms includes a detailed and stepwise diagnosis and investigation strategy with institution of appropriate antimicrobial treatment. Antimicrobial therapy should be tailored to the individual patient, accounting for local drug resistance patterns, antimicrobial sensitivities, and whether the infection is complicated or uncomplicated. All antimicrobial regimes should be combined with advice on preventing recurrence of infection. If treatment fails, further investigations and treatment should be considered.

KEY POINTS

1. Urinary infections are a significant cause of morbidity in women aged 20–65 years.
2. Infections can present with only 10^2 or 10^3 organisms/ml urine and even in the presence of sterile urine.
3. Up to 80% of recurrent infections are reinfection.
4. Approximately 25–30% of women will develop recurrent UTI not related to an underlying functional or anatomical abnormality.
5. The majority of UTIs are caused by facultative bacteria, and *E. coli* accounts for up to 70% of community-acquired infections.
6. Between 10% and 30% of women with asymptomatic bacteriuria develop acute pyelonephritis during pregnancy. This requires treatment as there is a risk of pregnancy-related complications.
7. Imaging should be considered in those with complicated infections and those whose temperatures do not resolve after 48 h of intravenous antibiotics.
8. Treatment should include advice on increasing fluid intake and perineal hygiene.

9. Symptomatic lower urinary infection requires at least a 3-day course of antibiotics.
10. UTI in a patient with a neuropathic bladder, indwelling catheter or ileal conduit should only be treated when it is symptomatic or if there is proven bacteriuria.
11. Training in catheter insertion and use should reduce the risk of catheter-associated infections. A closed-gravity-dependent drainage system should be employed.

INTRODUCTION	907	SUMMARY	917
INVESTIGATIONS	907	KEY POINTS	917
COMMON CONDITIONS AND TREATMENTS	909		

Introduction

There is emerging evidence of the interdependence of pathology and function between anterior, middle and posterior compartments of the pelvic floor. Many patients presenting to a gynaecologist or a coloproctologist have a mixture of urological, gynaecological and colorectal symptoms. The close anatomical, physiological and functional relationship between these compartments is reflected by the overlapping symptoms. Interventions to any one compartment may have an effect on the other compartments and may unearth a variety of new symptoms.

These close relationships have led to joint working in outpatient clinics and operating lists, and also to the emergence of multidisciplinary meetings. These can be held locally and regionally. They provide education for the members into the understanding of symptoms and treatment within the multidisciplinary field; meetings can be used to plan treatment and joint procedures, as well as for education (Mirnezami et al 2008).

A basic understanding of the anatomy and physiology of the colon, rectum and anus is essential in order to understand the symptoms associated with the posterior compartment (see Chapter 50).

Investigations

A detailed history and examination is often adequate to initiate basic treatment. It is always important to exclude serious pathology, and patients may require full bowel imaging of some sort (colonoscopy, barium enema or computed tomography colonography). In recent years, measurement of patient benefit from treatment has led to the use of incontinence and constipation scores which can be recorded before and after treatment. The Cleveland Clinic Incontinence Score (Table 59.1) is most commonly used.

The Cleveland Clinic Incontinence Score does not include aspects of urgency, but the Vaizey score (Vaizey et al 1999)

attempted to address this. Vaizey et al reported that urgency of less than 15 min is not usually a problem; however, when patients are not able to hold for more than 2 min, this has a significant impact on quality of life. A recent study (Cotterill et al 2008) took comments from a panel of seven clinical experts and from patients, and reported five key issues related to anal incontinence. These were unpredictability, toilet locations, coping strategies, embarrassment and restriction of social activities. This group are working on a new instrument to help validate treatments for anal incontinence based around quality of life as well as symptom severity.

Further investigations may be helpful to assess function and structure; they also provide essential evidence in some medicolegal cases.

Anorectal manometry

There are limitations to the reproducibility and reliability of anorectal manometry across institutions. However, a standardized protocol should be used within each institution. Tests are helpful in predicting realistic expectations from surgery and also in explaining the scope of problems to patients.

Anal manometry is not a single test but a series of measurements used to assess anal sphincter function, rectal sensation, rectoanal reflexes and compliance of the rectum (Kourakalis and Andromanakos 2004). The use of pull-through anal manometry allows assessment of the length of the functioning sphincter, resting pressures give a good estimation of internal sphincter function, and squeeze pressures assess external sphincter function. The patient is usually placed in the left lateral position, and manometry can be performed either using stationery pull-through or continuous pull-through techniques. Many catheters have four or eight channels, and these can therefore record different pressures in different parts of the external sphincter and internal sphincter at different levels. Using vector analysis, it is possible to look at the symmetry of the anal canal pressure, and

Table 59.1 Cleveland Clinic Incontinence Score

	Never	Rarely	Sometimes	Weekly	Daily
Incontinence: solid stool	0	1	2	3	4
Incontinence: liquid stool	0	1	2	3	4
Incontinence: gas	0	1	2	3	4
Lifestyle alteration	0	1	2	3	4
Wears pads	0	1	2	3	4

combining this with anal ultrasonography can show whether there is a structural as well as a functional problem in either of the sphincter muscles. The rectoanal inhibitory reflex is usually assessed during the physiology. Absence of this may indicate a longstanding problem such as Hirschsprung's disease. Rectal distension is assessed by inflating a balloon within the rectum; measurements are taken when the patient first feels the sensation of rectal filling, the feeling when there is maximum fullness, and then the feeling of urgent desire to defaecate. This can be extended to when the volume is unbearable. If the rectal threshold is low, even with a normal anal pressure, continence may be impaired.

Anal skin sensation is usually assessed by some form of electrical stimulation. Pudendal nerve terminal motor latencies are performed by stimulating the pudendal nerve transanally through the lateral wall of the rectum as the nerve transverses the ischial spine, using a St Mark's electrode on the tip of the examining finger. The normal delay between stimulation and recording is less than 2.2 ms and a longer delay suggests that there has been damage to the pudendal nerve. A lengthening of the pudendal nerve latency is often associated with poorer outcomes after surgery, and may suggest that the patient's incontinence is associated with nerve damage. An important outcome measure for sphincter repair is whether there is any pudendal neuropathy, as patients with pudendal neuropathy only have a 10% chance of success compared with 80% in patients without pudendal neuropathy (Laurberg et al 1988).

Ultrasound and dynamic imaging

The investigation of choice for structural abnormalities within the anal sphincter is a three-dimensional anal ultrasound. A data set can be captured and then manipulated at a later date to look at structural abnormalities throughout the anal canal (Figure 59.1).

Length of sphincter, damage to internal and external sphincters, and presence of sepsis or abnormalities can all be assessed.

Using the same anal probe transvaginally, it is possible to examine the levator plate and many other anatomical aspects of the pelvic floor. Asymmetry within the levator plate suggests damage during childbirth and often leads to the anus being diverted to the side of the damage (Figure 59.2).

Dynamic images of the bladder and rectum can be taken using an 8848 transvaginal scanner, looking for perineal descent as well as enteroceles, rectoceles and rectal intussusception.

Further assessment of the pelvic floor often requires some form of proctography. In order to assess the whole pelvic

**Figure 59.1** Three-dimensional anal ultrasound.**Figure 59.2** Transvaginal scan of pelvic floor.

floor using defaecating proctography, patients require not only contrast within the rectum but also in the small bowel, vagina and bladder. Defaecatory magnetic resonance imaging (Figure 59.3) can show all these parts of the pelvic floor. There are very few open magnets where a patient can sit and defaecate; therefore, the majority of these studies are performed with the patient lying prone.

Figure 59.3 Rectocele seen on dynamic magnetic resonance imaging.

It has been shown that magnetic resonance proctography shows increased evidence of other pelvic floor abnormalities over defaecating proctography. However, it underestimates the size of rectoceles and intussusception (Pilkington et al 2009).

Shapes study

By marking and counting the passage of ingested radio-opaque markers on a plain abdominal X-ray, it is possible to make an estimate of segmental and total colonic transit times. In a simplified method, 20 radio-opaque markers are ingested and an X-ray is taken at 60 and 96 h. Transit through the whole colon of more than 67 h is considered abnormal. Transit time is prolonged in 80% of patients suffering from constipation.

It is essential that all of these investigations are taken into consideration along with a full pelvic floor history and diary of bowel habit problems. Discussion at a pelvic floor multi-disciplinary team (MDT) meeting allows every compartment to be assessed in equal relevance.

Common Conditions and Treatments

Haemorrhoids

The term 'haemorrhoids' (also known as 'piles') is generally used to describe enlarged anal cushions which become symptomatic through symptoms of either bleeding or prolapse. However, correlation between symptoms and the treatment of haemorrhoids is poor. Haemorrhoids and associated symptoms are an extremely common problem, presenting in patients at general practitioners' surgeries and coloproctology clinics. During their lifetime, many patients will present with symptoms of rectal bleeding and many of these will have bleeding secondary to piles. It is most impor-

tant to ensure that there is no other treatable or more serious problem relating to this bleeding, such as cancer, polyps or inflammatory bowel disease.

Piles often present with a combination of symptoms, including itching, soreness, postdefaecatory leakage and lumps around the anus. It is thought that the sliding anal canal theory proposed by Thompson (1975) is the most likely cause of piles, where Treitz's muscle is stretched repeatedly resulting in fragmentation of the connective tissue. Haemorrhoids may be small and highly symptomatic, or large and asymptomatic. This is especially so in elderly female patients where normal anal canal pressures are low, and this can result in prolapse but little in the way of symptoms. Several classifications of haemorrhoids have been used over time. Goligher's classification (Goligher 1976) describes the degree of prolapse and whether these reduce spontaneously (grade 2), require manual reduction (grade 3) or are permanently prolapsed (grade 4). However, although this is good for the description, it does not consider the symptoms of the piles. Work by Lunniss and Mann (2004) has produced a more accurate and useful classification of haemorrhoids, dividing them into non-prolapsing and prolapsing, looking at not only the morphological presentation but also any additional features such as pruritus or pain.

The diagnosis of haemorrhoids relies on a good history, exclusion of other possible causes of these problems and then a thorough clinical assessment. Anal pain may be associated not only with haemorrhoids but also abscesses, fistulae or fissures. Discharge and pruritus may be associated with warts, hypertrophied anal papillae or rectal prolapse. Anal incontinence is usually secondary to internal sphincter dysfunction and a lump or prolapse. Inspection of the perianal area may be done with the patient either lying in the left lateral position or with legs up in a gynaecology chair. The presence of anal skin tags is often suggestive of previous episodes of haemorrhoidal prolapse. If the haemorrhoids are associated with a predominant feature of itching, skin may be macerated or discoloured, and the presence or absence of scars or previous surgery should also be determined.

Second- or third-degree piles may become evident on asking the patient to bear down, and fourth-degree piles should be obvious at the time of examination. Palpation of the rectum is essential in order to exclude any other pathology, although the piles themselves are not easily examined as, by virtue of the nature of the anal canal and the soft tissues, no lumps will usually be felt. However, at the time of digital examination, it is also prudent to examine both the squeeze and the resting pressure associated with the anal canal. A proctoscopy is essential in examining for haemorrhoids, although internal haemorrhoids may be well visualized using an internal flexible sigmoidoscope.

Treatment of haemorrhoids

Estimates of the proportion of the UK population affected with haemorrhoids range from 4.4% to 24.5%. In 2004–2005, approximately 23,000 haemorrhoidal procedures were carried out, and approximately 8000 of these were excision haemorrhoidectomies (National Institute for Health and Clinical Excellence 2007a).

Treatment of haemorrhoids can be divided into internal haemorrhoids (i.e. those above the dentate line) and external haemorrhoids (i.e. those below the dentate line and therefore covered with sensate epithelium).

Medical treatment for haemorrhoids

Patients with symptomatic but small internal haemorrhoids are best treated with dietary management; increasing the intake of fluid and fibre is the mainstay of this treatment. The typical symptoms of internal haemorrhoids are rectal bleeding and, sometimes, prolapse; avoiding straining by these dietary methods usually improves the symptoms. Dietary manipulation also improves rectal bleeding alone from grade 1 and grade 2 haemorrhoids, and this has been proven in three randomized controlled trials (Cataldo et al 2005).

Patients with persistent symptoms from grade 1, 2 or 3 haemorrhoids may benefit from an outpatient procedure. The most common procedure used and probably the most effective is haemorrhoidal banding. Other procedures that may be offered include sclerotherapy, infrared coagulation and cryotherapy. All of these treatments are aimed at decreasing the haemorrhoidal tissue volume and fixing the anal cushion back to the rectal wall. A meta-analysis of outpatient treatment suggested that rubber band ligation was the most effective of all outpatient procedures and was associated with a lower recurrence rate (MacRae and McLeod 1995). It is, however, relatively painful and the pain associated with the procedure increases with the number of rubber bands that are used to treat these piles. It is essential that the bands are placed well above the dentate line, or the immediate pain felt from the sensate epithelium is excruciating and patients will need to have these bands removed. Rubber band ligation is associated with a success rate of 65–85%, but follow-up at 5 years shows a relatively high recurrence rate. Following outpatient procedures for haemorrhoids, approximately 2% of patients report pain and less than 1% report urinary retention. Major complications include significant haemorrhage, which may take place immediately or as a secondary haemorrhage between postoperative days 7 and 10.

Thrombosed external haemorrhoids

Thrombosed external haemorrhoids are extremely painful and the thrombosis will settle; however, patients sometimes need intervention prior to spontaneous resolution of symptoms. External haemorrhoids do thrombose spontaneously and the exact aetiology remains unclear. Patients may be treated conservatively, especially if they present more than 3 days after the thrombosis occurred; actulose, analgesia and ice packs on the perineum will often resolve the symptoms more quickly than a surgical procedure.

Operative procedures for haemorrhoids

Haemorrhoidectomy of any sort should only be offered to patients with large external haemorrhoids or significant prolapse, or those who have been resistant to outpatient procedures. Open haemorrhoidectomy is effective; however, it is associated with pain, infection and other complications, such as incontinence and stenosis of the anal canal. More recently, patients have been able to undertake a less painful form of surgical procedure called a 'stapled haemor-

rhoidopexy'. The evidence for this has been reviewed by the National Institute for Health and Clinical Excellence (NICE) (2007a). A stapled haemorrhoidopexy is an intrarectal procedure that aims to reduce the prolapse of haemorrhoidal tissue by excising a band of the prolapse anal mucosal membrane above the dentate line using a specific circular stapling device (PPH03 Ethicon). The procedure is thought to interrupt the blood supply to the haemorrhoids and reduce the potential continuing prolapse of mucosa. The NICE review studied 27 randomized controlled trials of stapled haemorrhoidopexy and found that the procedure was associated with less pain up to 14 days following surgery, shorter wound healing times and significantly less postoperative bleeding. On the basis of the evidence in the literature, it was felt that a stapled haemorrhoidopexy offered benefits over a conventional haemorrhoidectomy in the reduction of short- and medium-term postoperative pain. However, although stapled haemorrhoidopexy is associated with a higher rate of recurrent prolapse, the committee concluded that 'a stapled haemorrhoidopexy should be recommended as a treatment option for people in whom surgical intervention is considered appropriate for the treatment of prolapsed internal haemorrhoids'.

Surgical haemorrhoidectomy can be performed open (Milligan-Morgan) or closed (Ferguson). During an open procedure, the haemorrhoid is dissected and the pedicle is either ligated or cauterized with diathermy; the wounds are left to heal by secondary intention. This may result in extreme discomfort and postoperative morbidity. The closed technique involves greater dissection but the wound is closed with a running suture.

Anal fissures

Patients with pelvic floor straining and post childbirth often present with anal pain associated with an anal fissure. An anal fissure is a tear running longitudinally in the epithelium of the anal canal, the majority of which lie posteriorly in the midline. Acute fissures are usually superficial, whereas chronic fissures may be associated with secondary changes including a sentinel tag or hypertrophied anal papilla. As with all acute and chronic anal conditions, efforts should be made to identify any precipitating causes or associated diseases (Crohn's disease or anal carcinoma). A recent consensus statement from the Association of Coloproctology of Great Britain and Ireland covers aspects of diagnosis and treatment (Cross et al 2008). The most common presenting features are pain during defaecation which may last for several hours afterwards, as well as rectal bleeding. The most consistent finding on examination is spasm of the anal canal, and it is uncertain whether this is the result of or due to ischaemia. Many of the management options have been based around reducing the internal anal spasm, but as with many benign anal conditions, one of the most important measures is to increase dietary fibre and adequate fluid intake. The majority of fissures, especially posterior fissures, are associated with a high resting pressure and a low blood flow to the anoderm resulting from this spasm. However, postpartum fissures are usually anterior and may be associated with a rectocele. The scar formation may be associated with ischaemia; however, the resting pressures in these patients are usually low. If there are multiple

fissures or the fissures are not in the midline, a differential diagnosis of Crohn's disease, ulcerative colitis, human immunodeficiency virus and associated infections as well as neoplasia should be considered. An anal fissure may occur at any time in life but is most common between the second and fourth decades, with an equal distribution between men and women and a lifetime incidence of just over 11%. Inspection of the anus will usually reveal the fissure, and it is not usually possible to carry out any further examination due to the pain associated with the fissure.

Treatment of anal fissures

Acute anal fissures are usually treated conservatively with stool softeners and topical analgesics. Recurrence rates are reduced from 68% to 16% after continuing conservative management (Jensen 1987).

Medical therapies

The majority of medical therapies are aimed at relaxation of the internal anal sphincter, and this can be achieved using glyceryl trinitrate (GTN) ointment, diltiazem ointment or botulinum toxin.

Glyceryl trinitrate

GTN is a widely used drug that works by vasodilating and relaxing smooth muscle. It is suggested that patients should be treated with 0.2% or 0.4% GTN two to three times per day, and healing will occur in approximately 60% of patients in the short term. Unfortunately, the side-effect of severe headaches often precludes usage, although these headaches do wear off with time (Cross et al 2008).

Calcium channel blockers

Diltiazem and nifedipine cause muscle relaxation and vascular dilatation by inhibiting the entry of calcium ions. Diltiazem 2% used topically is rarely associated with the GTN headache, and healing rates are similar to those seen with GTN.

Botulinum toxin

Botulinum toxin works by binding irreversibly to the presynaptic nerve terminals preventing acetylcholine release and resulting in hypotonia and a reduced resting anal pressure. The effects last for 2–3 months until the acetylcholine has reaccumulated in the nerve terminals (Jones et al 2003). The majority of people use 20 units of botulinum toxin, although the dosages reported in the literature vary between 10 and 100 units; healing rates of 40–100% have been reported. Botulinum toxin is given in two doses into the internal sphincter, and 75% of patients will be healed using this treatment.

Surgery

If these conservative and medical treatments have failed, patients may require surgery. Surgical options include lateral sphincterotomy which permanently divides the internal sphincter, fissurectomy and advancement procedures. Lateral sphincterotomy has a reported cure rate of approximately 85%; however, the downside of this procedure is a significant incontinence problem, with up to 30% of patients having difficulty in controlling wind and at least 3–5% of

people suffering from overt incontinence (Garcia-Aguilar et al 1996). If a sphincterotomy is performed, it should be limited to the length of the fissure as this almost certainly reduces the incontinence problems. If the patient has a short anus or has had previous anorectal surgery, extreme caution is advised.

Fissurectomy

Excising the fissure and the fibrotic edge may improve healing rates and can be used in association with botulinum toxin.

Anal advancement flap

In patients in whom the fissure is associated with a low pressure, any medical or surgical aims to reduce anal pressure are unlikely to cause healing. Therefore, these patients should usually have some form of V–Y advancement flap or rotational flap, and although the results can be good, there may be problems with infection and wound healing at the donor site.

Faecal incontinence

Faecal incontinence is a debilitating symptom or sign which occurs in 1–10% of adults. It is largely a hidden problem due to embarrassment, and may be a result of many contributing factors. Recent NICE guidelines recognized that the treatment of this problem should be patient centred, and will vary considerably between patients according to their lifestyle and culture (National Institute for Health and Clinical Excellence 2007b). One of the recommendations is that people who are reported to have faecal incontinence should be offered care which is managed by appropriate healthcare professionals, and these people should have relevant skills, training and experience. They should also work within an integrated continence service. Groups who are at very high risk of faecal incontinence include frail, older people; people with loose stools from any cause; women following childbirth, especially after a third- or fourth-degree tear; and patients with pelvic organ prolapse or rectal prolapse. Other groups include patients with cognitive impairment or learning difficulties, and those who have undergone pelvic radiotherapy. It is essential to be aware that faecal incontinence is a symptom, not a disease, and there are many contributing factors; there is not usually a primary diagnosis.

Assessment

The baseline assessment of these patients should include a relevant medical history, examination and anorectal examination. Once again, the focus should be on warning signs for a lower gastrointestinal cancer, prolapse, acute disc prolapse or cauda equina syndrome (which would be associated with anal sensation loss), and potentially treatable causes of diarrhoea. The long-term management of patients with incontinence should include a 6-monthly review of symptoms, and giving patients contact details of all relevant support groups as well as advice about continence products, skin care and how to communicate with their friends and families. It is of utmost importance to preserve dignity and offer emotional support as well as psychological support, as appropriate.

The history should focus on differentiation between urge, passive and postdefaecatory leakage. A full assessment of obstetric history, trauma and surgery to the perineum, previous pelvic surgery, back problems/surgery and medical conditions (diabetes and neurological conditions) is essential. Examination should focus on an abdominal examination and a full pelvic floor examination, including anterior and posterior compartment. Sigmoidoscopy and proctoscopy is essential to examine for rectal and anal pathology.

Investigations specific to incontinence include anorectal physiology, anal and perineal ultrasound, and sometimes magnetic resonance proctogram.

Initial management

It is important to explain to patients that there is no 'quick fix' for incontinence, and a range of treatments and interventions may be necessary. The mainstay of initial treatment is alteration of stool consistency in order to try to reduce wind and avoid soft bowel motions. Patients should still be encouraged to drink at least 1.5 l of fluid per day unless contraindicated, and one of the best routes for reducing bowel frequency is to limit wheat fibre or insoluble fibre intake, as well as reducing the intake of caffeine and fizzy drinks. It is often useful to get the patient to diary their problem (i.e. stool consistency, number and types of leakage or urge incontinence episodes), and to encourage them to alter one part of their diet or management at a time. It is then possible to decide whether this alteration has been appropriate or helped their incontinence problem. Patients who have urge incontinence with soft stools or even normal stools often do very well with a very low dose of loperamide hydrochloride. This comes in a syrup, which allows patients to closely titrate the amount of loperamide (2 teaspoons = 1 tablet). Occasionally, patients develop abdominal pain with this; these patients should be offered codeine phosphate or co-phenotrope instead. Patients should not be offered loperamide if they have an acute flare of ulcerative colitis, hard or infrequent stools, or diarrhoea without a diagnosed cause. It is usually beneficial to start the loperamide at 1 teaspoon or less, and to advise patients to use the loperamide to manipulate their bowel movements and consistency, rather than allowing their bowel movements to control their lifestyle.

Many of these patients who are post childbirth have poor pelvic floor muscles and a reduced rectoanal angle which contributes to their incontinence. These patients should be referred for physiotherapy, electrical stimulation and management within the continence advisory service. This gives them access to a group of professionals who are readily available to help manage their needs for pads and anal plugs, and who can then provide a link back into secondary health care when appropriate.

Patients who continue to have episodes of faecal incontinence after this initial management may need to be referred to a specialist continence service where they can undertake pelvic floor retraining, bowel retraining, biofeedback, electrical stimulation and rectal irrigation. Rectal irrigation is particularly beneficial for those who have poor emptying as well as incontinence, and two types of pumps are readily available: the Braun irrimatic pump and the Peristeen pump (Coloplast). In order for these systems to be useful, patients

need to have the ability to insert a tube into the rectum and manage the irrigation system.

Further treatment

All patients with faecal incontinence who are being considered for surgery should be referred to a specialist colorectal surgeon, who can offer the surgical and non-surgical options and discuss the realistic and likely outcome of any surgical intervention. Patients with a full-length external anal sphincter defect (which can be assessed on three-dimensional ultrasound) which is 90° or greater may be considered for an overlapping sphincter repair. This is done through a transperineal incision (Figure 59.4), and good long-term results at 5 years of 70% improvement should be expected. However, results deteriorate with time (Table 59.2). Patients with a Cleveland Clinic Incontinence Score below 9 should not be offered this as there is also a 15–20% risk that these patients will remain the same or be made worse. If patients have an incomplete internal sphincter defect, pudendal neuropathy, loose stools or irritable bowel, these are likely to decrease the effectiveness of a sphincter repair.

Patients in whom sphincter surgery is deemed inappropriate (i.e. those who have an intact anal sphincter, those in whom sphincter disruption is small, or where there is an absence of much in the way of voluntary contraction) may be referred for sacral nerve stimulation.

Sacral nerve stimulation

Sacral nerve stimulators have revolutionized the treatment of anal incontinence, and probably work through stimulation of both the external sphincter and the pelvic floor. Patients with significant anal incontinence are asked to keep a 2-week diary (Figure 59.5) about their episodes of incontinence. They have a test or trial of a percutaneous nerve stimulator, placed through S3 (or S2 or S4), and are asked to rediary their bowel movements during the 2 weeks of stimulation.

Results suggest that 70–80% of incontinent patients (urge and passive) will benefit from sacral nerve stimulation. If the trial is successful, these patients should be offered a permanent sacral nerve stimulator. This process involves implantation of a battery connected to a tyned wire which is inserted through the sacral foramen under X-ray guidance. The wire is tunnelled back to the battery, which is placed in the buttock or, occasionally, on the abdominal wall. Between 90% and 95% of patients who have at least a 50% improvement in symptoms with a temporary wire have a benefit with the permanent sacral nerve stimulator. There is a risk of infection, lead displacement and non-functioning of the permanent wire. NICE guidelines (National Institute for Health and Clinical Excellence 2004) looked at the results in 266 patients who had a sacral nerve stimulator; complete continence was achieved in 41–75%, and 75–100% of patients experienced a decrease of 50% or more in the number of incontinence episodes. As well as the incontinence, there is an ability to defer defaecation, which was absent previously, and an improvement in general quality of life. Adverse events in the fitting of the permanent implant are low (13%), mostly involving infection (three out of 149), lead migration (seven out of 149) and pain

(six out of 149) (National Institute for Health and Clinical Excellence 2004).

Graciloplasty and artificial bowel sphincter

If sphincter repair and sacral nerve stimulation have failed after full maximization of medical treatment, alternatives include a stimulated graciloplasty or an artificial bowel sphincter. Stimulated graciloplasty involves making a new anal sphincter using the gracilis muscle, which is transposed

after dissecting it off its attachments on the medial aspects of the tibia. The muscle is then wrapped around the anus and reattached on to the ischial tuberosity. Electrodes are implanted into the transposed muscle and stimulated continuously in order to change the muscle fibres from type 2 to type 1 (smooth muscle).

In 2006, NICE looked at a systematic review of 37 studies of graciloplasty and found that 42–85% of patients are continent after the procedure (National Institute for Health and

Clinical Excellence 2006). One case series reported a successful outcome in 72% of patients at 5-year follow-up. One of the most common complications of this procedure is wound infection (overall rate of 28%, with 15% requiring hospitalization). Electrical or technical problems also occur in 48% of patients; one of the side-effects of the procedure is problems with evacuation resulting in obstructive defaecation. The procedure is recommended but only if performed in specialist units and in carefully selected patients in whom other treatments have failed.

Artificial anal sphincters were adapted from approved urinary sphincters. They have been associated with high levels of infection and mechanical failure. Recently, in an attempt to avoid these septic complications, Finlay et al (2004) developed a transabdominal artificial bowel sphincter with a control balloon reservoir in the abdominal space. An inflatable cuff keeps the anal canal closed, and the patient presses a control pump in the abdominal wall which deflates the cuff in order to evacuate the bowel. Repressing the button closes the sphincter again by allowing the fluid to return into the cuff. In a series of 12 patients with follow-up of 59 months, 75% of patients had a functioning implant and the continence scores were improved from 16 to 3 after surgery. Three out of 12 patients had to have the device removed because of complications, and it is recommended that this procedure should only be performed under strict audit and clinical governance conditions and in units with specialist interest in faecal incontinence (National Institute for Health and Clinical Excellence 2008a). However, it may be a promising route for patients with severe faecal incontinence.

Injectable bulking agents

Few long-term data are available for the use of bulking agents in passive leakage or incontinence. Injections of a variety of bulking agents (collagen, carbon beads and silicon particles) have been used. They are usually injected submucosally in three or four places, just above the dentate line (where the anal canal is less sensate and therefore less

painful), in order to try and reproduce the anal cushions and stop passive leakage. The largest case series has shown that 82 patients had significant continence score improvement in 6–12 months (Tjandra et al 2004). The largest case series showed that the most common complications are pain, minor ulceration and, occasionally, infection, as well as leakage of the substance from the anus. NICE guidance suggests that the evidence is not adequate for bulking agents to be used without special arrangements for consent, audit and research, and these procedures should only be performed in units specializing in faecal incontinence that have the ability to audit these results and inform patients of the potential lack of evidence (National Institute for Health and Clinical Excellence 2007c).

Stoma

Patients who fail all of the above procedures may require a stoma, and in many circumstances, colostomies can improve quality of life and decrease the amount of time organizing bowel care. Nowadays, An end colostomy can be performed laparoscopically. Although it is a relatively simple procedure, there are complication rates of between 25% and 75%. Often, patients experience problems with skin irritation, retraction and bleeding from the stoma, as well as problems with the bag sticking. However, the most common problems in the long term are parastomal hernias, stenosis and prolapse.

Rectal prolapse surgery for full-thickness rectal prolapse

A full-thickness rectal prolapse is an extremely distressing and uncomfortable condition. It occurs most frequently in elderly ladies, and the quality of life of these patients can be severely compromised. Occasionally, there are complications such as gangrene and perforation, but the majority of patients have symptoms of a heavy feeling, mucus leakage, bleeding and recurrent prolapse through the anus. This may be associated with other pelvic floor prolapses such as uterine prolapse. In younger age groups, full-thickness rectal prolapse may be associated with previous eating disorders,

and although the cause is not known, it is suspected that this may be due to a problem of collagen formation. The only possible curative treatment for a full-thickness rectal prolapse is surgery, but if a patient is relatively asymptomatic, surgery can be avoided and patients can have their constipation treated with a stool softener. Surgical interventions are based on either 'chopping off the prolapse' or 'hitching it up'. When hitching it up (rectopexy), a resection of the sigmoid may also be undertaken if there is associated constipation. A recent Cochrane analysis (Tou et al 2008) looked at a series of five different types of intervention, with the outcome measures being morbidity, length of stay and mortality. Unfortunately, the number of studies available was extremely small, and most of the randomized controlled trials included few patients. Twelve studies were included in this work with a total of 380 participants. Patients who are fit should be offered a laparoscopic or open rectopexy; these are associated with lower recurrence than a perineal procedure. Frail and unfit patients should have a perineal procedure (i.e. Altemeier operation or Delorme's procedure), the results of which suggest a recurrence rate of 25–40%. However, the morbidity and mortality associated with perineal procedures is low, and since many of these patients are over 80 years of age, this may make the recurrence rates relatively acceptable. If any form of prolapse is associated with a gynaecological prolapse, a combined procedure should be undertaken.

Altemeier operation

The design of this operation is to resect any prolapsing or redundant bowel and to attempt to recreate the pelvic floor by plicating the levators and reconnecting the sigmoid colon back to the anus with a coloanal anastomosis. However, there is no fixation of the rectum back up to the sacrum. The recurrence rate is approximately 16%, in comparison with 5% or less for an abdominal procedure (Tou et al 2008).

Delorme's procedure

The alternative perineal procedure is the Delorme's procedure, where the mucosa is resected off the bowel muscle tube. The bowel wall is then plicated and the mucosa of the anal canal is reanastomosed to the musosa high up within the anal canal. It is associated with a relatively high recurrence rate (up to 37%) (Tou et al 2008).

Rectopexy

The rectopexy has a much lower recurrence rate (<10%), and although mucosal prolapse is a relatively common form of recurrence, full thickness rarely occurs. The rectum is dissected down to the pelvic floor and then fixed up to the presacral fascia. Nowadays, this is mainly done laparoscopically and with sutures, but meshes and sponges were used for this fixation in the past.

In summary, healthy patients or patients with low comorbidity should probably have an abdominal or laparoscopic approach to treat their rectal prolapse with some sort of fixation. If there is any evidence of constipation, sigmoid resection with proctopexy is the preferred choice. However, there is a risk of an anastomosis and potential leak. In high-risk patients, a perineal approach should be offered and this varies culturally between an Altemeier's operation (often performed in the USA) and a Delorme's procedure (tends to be favoured in the UK).

Solitary rectal ulcer syndrome

This is a rare syndrome associated with rectal straining, resulting in an ischaemic, ulcerated wall of the rectum. This usually occurs anteriorly. The symptoms which then develop include further straining, a feeling of incomplete emptying, rectal bleeding and the passage of mucus as well as pain. On clinical examination, there is often a single or occasionally multiple ulcers, which are shallow. Occasionally, this may present as a polypoid lesion, which can be confused with the gross appearance of a carcinoma or a large polyp. A biopsy will confirm the diagnosis. Treatment is aimed at preventing straining and further chronic damage. Internal intussusception is found in a large number of these patients, but it is difficult to know whether this is related to solitary rectal ulcer formation or a result of the long-term straining. The mainstay of treatment is biofeedback aimed at reducing the length of time on the toilet. Straining patients are told how and where to sit and are given psychological support. They may require repeated courses of biofeedback as the results tend to fade after 2–3 years. Many people have tried a variety of surgical treatments for these ulcers, including local excision, rectopexy, stoma and even anterior resection. However, it has been found that resection is unlikely to improve the problem, and the majority of the surgical procedures result in less than 50% of the patients being cured. Even formation of a stoma may not relieve the symptoms. The patient will still have tenesmus and feel the need to defaecate continually.

Chronic constipation

Constipation in adults is extremely common and may be associated with a variety of abdominal symptoms as well as perineal discomfort.

Rome criteria for constipation

Constipation is defined as the presence of two or more of the following symptoms:

- Straining during at least 25% of defaecation.
- Lumpy or hard stools in at least 25% of defaecation.
- Sensation of incomplete emptying for at least 25% of defaecation.
- Sensation of anorectal obstruction blockage for at least 25% of defaecation.
- Manual manoeuvres to facilitate at least 25% of defaecation (such as digital evacuation support of the pelvic floor).
- Fewer than three bowel movements a week.
- Loose stools are rarely present without the use of laxatives.

Criteria have to have been met for the previous 3 months with the onset of symptoms 6 months prior to diagnosis.

Constipation occurs in up to 30% of the population (Garrigues et al 2004), and females have a higher incidence than males. Physical exercise and a high fibre diet are protective against constipation. Constipation can be divided into slow transit constipation, obstructive defaecation syndrome and irritable bowel syndrome (IBS).

Simple causes of constipation include a low fibre diet, dementia, depression and eating disorders. There are

metabolic causes such as hypothyroidism, hypokalaemia, hypercalcaemia and diabetes mellitus (McCallum et al 2009). Neurological problems can include multiple sclerosis and Parkinson's disease, and there are a variety of drug-related causes for constipation. Patients with painful anorectal conditions such as fissures, haemorrhoids, fistulas etc. may develop constipation secondary to their painful anus. The majority of cases of constipation can be treated with basic dietary advice. Patients should sit on the toilet with their feet raised so that they sit in a semi-squatting position; this opens up the anorectal junction and allows them to defaecate more effectively. The use of abdominal massage and exercises which can be provided through a specialist nurse practitioner can help with the process of defaecation. Patients should ensure that they are well hydrated and take adequate amounts of fluid as well as exercise. Fibre may be beneficial, although patients with constipation related to IBS may find that their abdominal pain is increased with their intake of fibre. Preferred laxatives include movicol and magnesium hydroxide which do not rely on gut stimulation. However, stimulant laxatives are sometimes of use in patients who have poor colonic motility, especially secondary to opiates (McCallum et al 2009).

Obstructive defaecation

'Obstructive defaecation' is a term coined to indicate that a patient has stool in the rectum but is unable to evacuate it. The cause may be functional or anatomical. Anatomical problems include a rectocele, possibly an intussusception, enterocele, sigmoidocele and rectal prolapse. Functionally, patients may have paradoxical contractions of the pelvic floor or an inability to relax the anus which stops them from defaecating. Patients will complain of a feeling of incomplete evacuation, and will often need to digitate rectally or vaginally. A rectocele or pelvic floor weakness may be assessed clinically, but magnetic resonance defaecography is useful to see a non-emptying rectum. An additional investigation is colonic transit studies which may suggest that there is slow transit constipation.

Treatment of obstructive defaecation

Conservative treatment of obstructive defaecation includes bulking of the stools so that there is increased pressure of stools from above. Physical exercise and the use of suppositories or enemas may aid evacuation. More recently, rectal irrigation using either the Braun irrigator pump or the Peristeen pump has been shown to aid patients who have both functional and structural problems within the pelvic floor. Behavioural therapy with biofeedback training teaches patients to coordinate the muscles required to defaecate. Rectoceles sometimes present to a coloproctologist along with a history of obstructive defaecation, and repairs may include the traditional transvaginal, transperineal or transanal route. More recently, coloproctologists have been using a stapled transanal rectal resection for patients with a combined rectocele and rectal intussusception. A British national database of these patients has shown that these procedures may improve functional results in up to 88% of patients. There have been some problems with urgency,

especially in patients who had a degree of incontinence prior to their surgery.

Slow transit constipation

Slow transit constipation is often idiopathic or may be associated with a neuropathy or recent or previous pelvic surgery. Patients with a megacolon associated with slow transit constipation and a normal functioning rectum may do well with a subtotal colectomy and ileorectal anastomosis; satisfaction rates of up to 90% have been reported (Lubowski et al 1996). Segmental resection appears to be unsatisfactory, and those patients who have an associated megarectum may be better treated with a ileoanal pouch (Gladman et al 2005). More recently, there have been some promising results using sacral nerve stimulators in patients with slow transit and combined causes of constipation. This seems to work by retrograde stimulation of the parasympathetic and sympathetic nerve chain.

Irritable bowel syndrome

IBS is one of the most common gastrointestinal disorders with an estimated prevalence of 10–20%. Patients present with a very wide range of symptoms, many of which overlap with other gastrointestinal disorders. It is essential, as always, to exclude any other significant pathology that may be causing these symptoms, but over-investigation is associated with a poorer outcome. A patient should present with symptoms for at least 6 months for a diagnosis of IBS to be made. They usually have a history of abdominal pain or discomfort associated with bloating, and often a change in bowel habit. In order to make a diagnosis of IBS, the pain or discomfort should be relieved by defaecation, or be associated with altered bowel frequency or stool form.

At least two of the following should also be associated:

- altered ability to defaecate including straining, urgency or incomplete evacuation;
- abdominal bloating and distension;
- symptoms made worse by eating; and
- passage of mucus.

Patients do not need investigation with invasive tests, but should have a full blood count, erythrocyte sedimentation rate, C-reactive protein (CRP) and antibody testing for coeliac disease. Patients should only be referred for secondary care if they have associated symptoms of unintentional or unexplained weight loss, associated rectal bleeding, a family history of any bowel or ovarian cancer, or are over 60 years of age with a change in bowel habit lasting more than 6 weeks with looser and/or more frequent stools. Additional 'red flags' are anaemia, abdominal masses, rectal masses or raised CRP (National Institute for Health and Clinical Excellence 2008b).

Patients should be treated for their IBS symptoms by self-help; this means looking at lifestyle, physical activity, diet and symptom-targeted medications. An essential part of treatment of IBS is assessing diet and nutrition (this includes fibre intake, which should usually be reduced). Insoluble fibre, especially wheat fibre, seems to exacerbate patients' symptoms by creating more wind; if more fibre is needed in order to treat constipation-related IBS, patients should eat

Figure 59.6 Bristol stool chart.

foods high in soluble fibre (e.g. oat fibre). Other general dietary advice includes taking small meals regularly, eating meals slowly, avoiding missing meals and drinking at least eight cups of fluid per day, especially non-caffeinated drinks or water. Caffeine intake should be restricted, as should the

intake of alcohol or fizzy drinks. Fresh fruit should be limited to three portions per day, and if IBS is associated with diarrhoea, artificial sweeteners should be avoided, as should diabetic insulin products. Other management can be by pharmacological intervention, and the decision regarding which drugs should be used should be tiered to the predominant symptom. If pain is a problem, patients should be offered antispasmodic agents. For patients with constipation, laxatives should be given but fibre and lactulose should be avoided because of their wind and bloating aspects. If patients have diarrhoea-associated IBS, loperamide is the first-choice antimotility agent, and patients should be advised to adjust the dosage of laxative or antimotility agent to aim for a well-formed stool (type 4 on Bristol stool chart; Figure 59.6) (National Institute for Health and Clinical Excellence 2008b).

Second-line treatment, tricyclic antidepressants, may be used for pain relief, starting with an extremely low dose (5–10 mg) of amitriptyline, taken once at night. A selective serotonin reuptake inhibitor may be used if a tricyclic antidepressant is ineffective. Patients should be warned that side-effects of dry mouth and drowsiness may occur with these medications. Patients should not be referred to hospital or followed-up except on an annual basis unless symptoms change. NICE has published a full report of treatment options (National Institute for Health and Clinical Excellence 2008b).

Summary

In summary, there are many functional and structural bowel problems which occur alone and in combination with gynaecological and urological symptoms. Cancer and significant pathology should be excluded. A full history and examination, as well as some specific tests, will aid diagnosis and help to plan treatment. Patients should be assessed within a multidisciplinary team.

KEY POINTS

1. Anal manometry, electrophysiology and rectal sensation can provide valuable functional information on the anorectal complex. Combined with structural information from endoanal ultrasound, this allows the possibility of evidence-based management.
2. Evacuation proctography, isotope defaecography and colonic motility studies allow structural and functional assessment of defaecation which is vital for patient selection for surgery.
3. Faecal incontinence is an under-reported problem and there are multiple aetiologies. Obstetric injury is the most common cause of anal sphincter disruption, and although anal sphincter repair can be very successful, results are influenced by the extent of injury and the presence of pudendal neuropathy.
4. Assessment of constipation should include a detailed history and examination, combined with selective investigations. Management is predominantly conservative.
5. Joint assessment of patients with pelvic floor disorders in a combined pelvic floor clinic by a colorectal surgeon and a urogynaecologist is extremely valuable. Benefits include combined assessment, single hospital admission for complex joint surgery, and exchange of research ideas.

Introduction

Sexuality and its expression contribute to some of the most complex aspects of human behaviour. The expression of sexuality and intimacy remains important throughout the lifespan of a woman, and hence needs to be understood in health as well as in illness. Although sexual problems are highly prevalent, a very small proportion of women consult a physician. In a UK-based survey, 54% of women reported at least one sexual problem lasting for at least 1 month during the previous year, which caused 62% of them to avoid sex. Only 21% with problems had sought help, of which 74% consulted their general practitioner (Mercer et al 2003). A web-based survey of 3807 women in the USA revealed that the most important barriers for women to seek help were embarrassment and feeling that the physician would not be able to provide help. Only 42% of this cohort sought help from their gynaecologist (Berman et al 2003). The high prevalence of sexual dysfunction and reluctance of women to seek help is a reflection on physicians' attitudes and ability to communicate with female patients about their sexual function.

Research into female sexuality has been a neglected area. It was Kinsey's research in the 1950s on sexual practices in men and women that helped to dispel the myth that women are not interested in sex. However, it has taken a long time to accept that women have a right to sexuality. The advent of new therapies for male sexual dysfunction has led to recent interest in these problems in women. There are a number of reasons why research in the past has focused more on male sexual problems than female. Firstly, it has been difficult to measure appropriate endpoints in clinical trials due to a lack of valid outcome measures. Secondly, the

female sexual response is complex, as highlighted by current models (Figure 60.1) compared with the previously described linear models which were based on the relatively uncomplicated male sexual response cycle. The new, non-linear model of female sexual response considers emotional intimacy, sexual stimuli and relationship satisfaction (Basson 2001). This circular model demonstrates that many women initially begin a sexual encounter from a point of sexual neutrality. The decision to be sexual may come from a conscious wish for emotional closeness or as a result of seduction or suggestion from a partner. Women may have numerous reasons for engaging in sexual activity other than sexual drive. Sexual neutrality or being receptive to rather than initiating sexual activity is considered a normal variation of female sexual functioning. In addition, it is frequently the case that subjective and physiological sexual arousal precedes desire.

Definition and Classification

According to the World Health Organization's International Classification of Diseases (ICD-10) (World Health Organization 1992), the definition of sexual dysfunction includes 'the various ways in which an individual is unable to participate in a sexual relationship he or she would wish'. On the other hand, in the Diagnostic and Statistical Manual of Mental Disorders IV (DSM-IV) (American Psychiatric Association 1994), female sexual dysfunction (FSD) is defined as 'disturbances in sexual desire and in the psychophysiological changes that characterise the sexual response cycle and cause marked distress and interpersonal difficulty'. Although both systems recognize the need for a subjective distress criterion, these definitions rely on the linear human response cycle. Furthermore, both systems are based on conceptualization

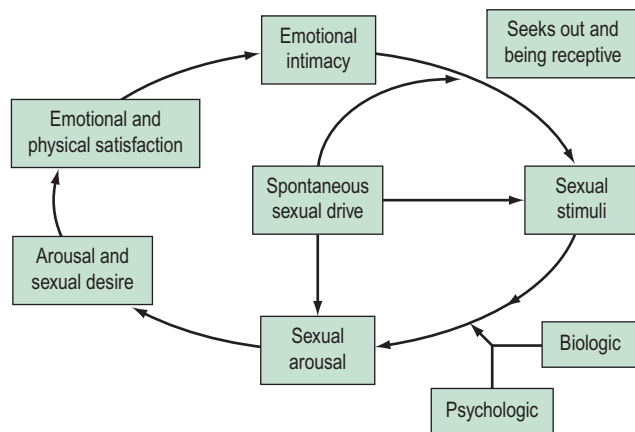

Figure 60.1 Female sexual response cycle.

Adapted from Kingsberg S, Janata JW (2007) *Female Sexual Disorders: Assessment, Diagnosis and Treatment*. *Urol Clin N Am* 34:497–506.

of sexual response as a 'psychosomatic process' involving psychological and somatic components. In 1998, the Sexual Function Health Council of the American Foundation devised the first consensus-based definition and classification system for FSD, which was further updated in 2003 (Basson et al 2004) (Box 60.1). FSD is best regarded as a spectrum of disorders with considerable overlap. Understanding this interplay of physical and psychosocial factors in context with illnesses, and medical and/or surgical interventions will help the clinician in managing FSD. Sexual dysfunction may arise because of an illness or disability, a medication or surgical procedure, changes accompanying the ageing process, relationship difficulties, abusive experiences, performance anxiety or any combination of factors such as these (Table 60.1).

Prevalence of Sexual Dysfunction in Women with Urogynaecological Problems

Sexual dysfunction occurs commonly in women attending urogynaecological services. Up to 64% of sexually active women attending a urogynaecology clinic suffer from FSD (Pauls et al 2006). Although it is a very common problem, a recent survey of members of the American Urogynecologic Society (AUGS) showed that only a minority of urogynaecologists screen all patients for FSD. Lack of time, uncertainty about therapeutic options and older age of the patient were cited as potential reasons for failing to address sexual complaints as part of routine history (Pauls et al 2005). A survey of the members of the British Urogynaecological Society (BSUG) using the same questionnaire with a few modifications reflected similar findings. Fifty percent of the BSUG members regularly screened for FSD at clinic visits and 49.5% after surgery, compared with 77% and 76% of AUGS members, respectively. The most important barrier for not enquiring about FSD was lack of time. Seventy-six percent found training for FSD to be unsatisfactory (Roos et al 2009). The similarity in trends between the UK and USA highlights that this may be a more global problem that needs wider exploration. Furthermore, the subject of FSD should be given more importance in the undergraduate and post-

Box 60.1 Definition and classification of FSD

Sexual interest/desire disorder

There are absent or diminished feelings of sexual interest or desire, absent sexual thoughts or fantasies, and a lack of responsive desire. Motivations (here defined as reasons/incentives) for attempting to have sexual arousal are scarce or absent. The lack of interest is considered to be beyond the normative lessening with lifecycle and relationship duration.

Arousal disorder

Subjective sexual arousal disorder

Absence of or markedly diminished feelings of sexual arousal (sexual excitement and pleasure) from any type of sexual stimulation. Vaginal lubrication or other physical response still occur.

Combined genital and subjective arousal disorder

Absence of or markedly diminished feelings of sexual arousal (sexual excitement and pleasure) from any type of sexual stimulation, as well as complaints of absent or impaired genital sexual arousal (vulval swelling, lubrication).

Genital sexual arousal disorder

Complaints of absent or impaired genital sexual arousal. Self-report may include minimal vulval swelling or vaginal lubrication from any type of sexual stimulation, and reduced sexual sensations from caressing genitalia. Subjective sexual excitement still occurs from non-genital stimuli.

Persistent sexual arousal disorder

Spontaneous intrusive and unwanted genital arousal (e.g. tingling, throbbing, pulsating) in the absence of sexual interest and desire. The arousal is unrelieved by one or more orgasms, and the feelings of arousal persist for hours or days.

Orgasmic disorder

Despite the self-report of high sexual arousal/excitement, there is either lack of orgasm, marked diminished intensity of orgasmic sensations or marked delay of orgasm from any kind of stimulation.

Sexual pain disorders

Dyspareunia

Recurrent or persistent pain with attempted or complete vaginal entry and/or penile vaginal intercourse.

Vaginismus

The persistent or recurrent difficulties of the woman to allow vaginal entry of a penis, a finger and/or any object, despite the woman's expressed wish to do so. There is often (phobic) avoidance and anticipation/fear/experience of pain, along with variable involuntary pelvic muscle contraction.

Other sexual pain disorders

Recurrent or persistent genital pain induced by non-coital sexual stimulation.

graduate curriculum, so that clinicians enquire about this embarrassing problem.

Aetiology of Sexual Dysfunction in Women with Pelvic Floor Dysfunction

In a survey of 104 patients attending a urogynaecology clinic (Sutherst 1979), 46% admitted that their urinary disorder

Table 60.1 Conditions that affect female sexual function and their effects

Effect(s)	
Condition	
Oestrogen deficiency e.g. menopause, secondary amenorrhea (binge-eating disorders, rigorous diet), puerperal amenorrhoea (lactational amenorrhoea), contraception with super-light pills, menopause	Decreased lubrication and arousal
Testosterone deficiency e.g. premature iatrogenic menopause	Decreased desire
Diabetes	Decreased lubrication
Hormonal disorders e.g. thyroid, pituitary, adrenal	Decreased lubrication and desire
Neurological disorders e.g. Parkinson's disease, multiple sclerosis	Decreased lubrication, arousal, desire and difficulty reaching orgasm
Genital prolapse	Decreased desire and arousal
Urinary incontinence	Decreased desire, arousal and pain
Atrophy, vaginitis, pelvic inflammatory disease, endometriosis, vestibulitis, cystitis	Pain and vaginismus
Arthritis	Limitation of movement
Trauma, sexual assault	Arousal disorder
Procedure	
Oophorectomy	Decreased desire and lubrication
Episiotomy and pelvic floor repairs	Pain
Drugs	
Antihypertensives e.g. β -blockers, α -blockers, diuretics	Decreased desire and difficulty reaching orgasm
Psychotherapeutic drugs e.g. tricyclic antidepressants, selective serotonin reuptake inhibitors, lithium, benzodiazepines	Difficulty reaching orgasm
Hormones e.g. oral contraceptives, oestrogens, progestins, gonadotrophin-releasing hormone agonists	Decreased desire
Cardiovascular agents e.g. lipid-lowering agents, digoxin	Decreased desire
Chemotherapeutic agents	Vaginal dryness, decreased desire and difficulty reaching orgasm

had an adverse effect on sexual relations. The reasons for reduced frequency of sexual intercourse were superficial or deep dyspareunia (most common), wetness at night and the need for protection of a towel all the time, leakage of urine during coitus, decreased libido, depression or embarrassment, marital discord and the need for separate beds.

Women with pelvic organ prolapse may have sexual dysfunction due to mechanical obstruction. However, the reasons probably extend beyond the local effects. It has been shown that women seeking treatment for advanced prolapse have poorer body image and quality-of-life scores compared with women with normal vaginal support (Jelovsek and Barber 2006). Using the female sexual response cycle, one can conceptualize how incontinence and prolapse may affect sexuality. Arousal may be reduced in a woman with coital incontinence or prolapse due to embarrassment. This, in turn, affects orgasm and can also lead to reduced lubrication. Sexual intercourse in this situation will cause the woman to experience pain, which may affect arousal (Figure 60.2).

Surgery for prolapse and urinary incontinence has a role in reconstructing the local anatomy and alleviating symptoms. This, however, does not necessarily ensure optimal sexual function. The cause of sexual dysfunction following vaginal surgery may be classified into organic and/or psychosocial. Organic causes are anatomical, physiological, vascular, neural and hormonal. It can be hypothesized that surgical disruption of the iliohypogastric and/or pudendal arterial blood may result in compromised blood flow, which may cause vaginal dryness and dyspareunia. The anterolateral vaginal walls are densely innervated by pelvic autonomic nerves which are critical for preserving sexual function. Surgery in this region for stress urinary incontinence and cystocele repair may affect this innervation and alter sexual experience. Damage to the dorsal nerve of the clitoris due to its close proximity while performing surgery in the anterior compartment (various sling procedures) may cause impairment of orgasmic function. Vaginal narrowing and shortening, especially following posterior repairs, may cause dysfunction. Concomitant procedures such as oophorectomy may cause loss of a physiological testosterone milieu with a subsequent decrease of sexual libido, pleasure and sense of well-being. In addition, coexisting psychosocial factors such as life stressors, anxiety and depression need to be borne in mind. Altered perception of genital health, both by the woman and her partner, after surgery with associated apprehension and fear of damage to the internal organs can also be contributory factors for a negative impact on sexual function.

Relationship between Pelvic Organ Dysfunction and Sexual Function

Evidence from large prospective studies has demonstrated that prolapse and/or incontinence have an adverse effect on sexual function (Rogers et al 2001a, Handa et al 2004, Novi et al 2005). Complaints of stress urinary incontinence, overactive bladder (OAB) and lower urinary tract symptoms have been shown to have a negative impact on all domains of sexual function (Salonia et al 2004, Aslan et al 2005). The most common sexual complaints in women with urinary incontinence are low desire, vaginal dryness and dyspareunia (Handa et al 2004). Amongst the different types of urinary incontinence, OAB has a particularly high association with sexual dysfunction, which could be indicative of an underlying psychosomatic disorder.

Using a validated questionnaire, Novi et al (2005) demonstrated significantly lower measures of sexual function in

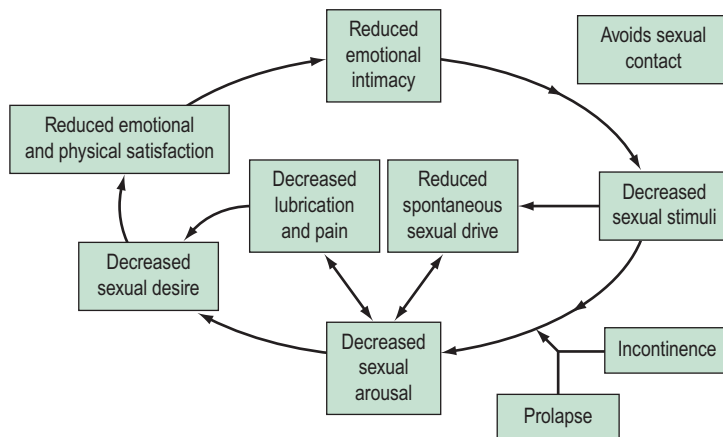

Figure 60.2 Possible effects of incontinence and prolapse on the female sexual response cycle.

women with pelvic organ prolapse. Women with prolapse were more likely to have urinary and/or faecal incontinence during sexual activity, more dyspareunia and fewer orgasms. They were also more likely to report negative emotional reactions associated with sex, and higher rates of embarrassment leading to avoidance of sex. Presence of both prolapse and incontinence has a cumulative negative effect on sexual function, with libido, sexual excitement and orgasm being significantly affected (Ozel et al 2006). Increasing severity of prolapse is associated with symptoms related to urinary incontinence, voiding, and defaecatory and sexual dysfunction, which do not necessarily correlate with the location of prolapse and therefore are not compartment specific (Ellerkmann et al 2001).

Effect of Treatment of Pelvic Floor Dysfunction on Sexual Function

Assuming that the physical effect of prolapse and incontinence is one of the contributing factors for sexual dysfunction, one could logically assume that an intervention leading to their improvement should improve sexual function.

Urinary incontinence

Pelvic floor rehabilitation appears to positively influence female sexuality. Zahariou et al (2008) evaluated the effect of a programme of supervised pelvic floor muscle training on sexual function, in a group of women with urodynamically diagnosed stress urinary incontinence, using a validated questionnaire (Female Sexual Function Index, FSFI) 12 months after treatment. All domains of the FSFI improved significantly, with median total FSFI scores increasing from 20.3 to 26.8. The improvement in sexual function could be due to the improvement in strength of the pelvic floor muscles. Pelvic floor contraction plays an important role in female orgasmic response. Furthermore, the strength of the pelvic floor muscles probably affects the anatomical position of the clitoral erectile tissue, with consequences for sexual stimulation. In addition, muscle training improves muscle morphology and neuromuscular function. Although there are extensive data on the effect of various pharmaceutical agents in women with OAB, sexual function has only been

evaluated in one study (Sand et al 2006). The Multicentre Assessment of Transdermal Therapy in Overactive Bladder with Oxybutynin study was an open-label, prospective trial of 2878 subjects with OAB, treated with transdermal oxybutynin for 6 months or less. The impact of OAB on sexual function before and after treatment was assessed via item responses from the King's Health Questionnaire and Beck Depression Inventory-II. At baseline, 23.1% of participants reported that OAB had an impact on their sex life. Coital incontinence in 22.8% of women decreased after treatment to 19.3%. The effects of OAB on subjects' sex lives improved in 19.1% of cases (worsened in 11.2%), and the effect on relationships with partners improved in 19.6% of cases (worsened in 11.9%). Reduced interest in sex, reported by 52.1% of women at baseline, improved significantly. Considering that sexual dysfunction is highly prevalent in women with OAB, it is surprising that such scarce data are available.

Prior to introduction of the minimally invasive sling suburethral procedures, the Burch colposuspension was regarded as the 'gold standard' surgical treatment option for stress urinary incontinence. Considering that the procedure was used for many decades, there are few data on the impact of colposuspension on sexual health. Moran et al (1999) evaluated 55 women with stress urinary incontinence who reported coital incontinence before undergoing colposuspension. Preoperative coital leakage occurred in 65% of women with penetration, 16% with orgasm and 18% with both. After surgery, 81% of the women reported no coital incontinence. Similarly, Baessler and Stanton (2004) showed that 6 months after colposuspension, while stress urinary incontinence improved in 77% of patients, coital incontinence was cured in 70% and improved in almost 7%, which suggests that coital incontinence is likely to be cured when urinary incontinence is successfully treated by Burch colposuspension.

Recent prospective studies of surgery for urinary incontinence using tension-free vaginal tape have found a positive impact on sexual function, primarily because of cure of coital incontinence with the associated emotional benefits of loss of fear and embarrassment due to leakage (Shah et al 2005, Ghezzi et al 2006). Causes of postoperative worsening of sexual function have been attributed to loss of libido, dyspareunia and partner discomfort. Cases of dysfunction

due to vaginal erosion of the mesh and de-novo anorgasmia are infrequent. A recent study based on a postal questionnaire survey has shown that the transobturator tape (TOT) procedure can have a positive, but also a negative, outcome on female sexual function (Sentilhes et al 2008). Comparing the TOT procedure with the transvaginal approach, Elzevier et al (2008) found that both procedures had a positive effect on sexual function due to improvement in incontinence. However, pain due to vaginal narrowing was significantly more common in the TOT procedure group.

Prolapse

Sexual activity in women with pessaries *in situ* is poorly studied. It has been shown that long-term pessary use is acceptable to sexually active women. Using the FSFI questionnaire, Kuhn et al (2009) showed that desire, lubrication and sexual satisfaction improved significantly, and orgasm remained unchanged in women who used pessaries for pelvic organ prolapse and were sexually active.

Anterior repair does not seem to have an effect on sexual function unless it is combined with another procedure. Colombo et al (2000) reviewed 23 women who had an anterior repair for cystocele and stress urinary incontinence 8 years after surgery, and found that 56% had mild-to-severe postoperative dyspareunia. However, all patients in this study also had a posterior repair and perineorrhaphy. Most studies on vaginal surgery in the posterior compartment for rectocele repair have demonstrated improvement in sexual function, with a decrease in dyspareunia when only midline fascial plication or site-specific repair was done (Cundiff et al 1998, Kenton et al 1999, Porter et al 1999, Glavind and Tetsche 2004). However, when the repair involved levator plication, there was a significant increase in dyspareunia following surgery (Kahn and Stanton 1997).

Vaginal vault prolapse surgery is difficult to study as the problem usually involves multiple compartments of the pelvic floor. However, the Colpopexy and Urinary Reduction Efforts trial (Handa et al 2007) provided a unique opportunity to study sexual function in women undergoing sacrocolpopexy with and without colposuspension. Using a validated questionnaire [Pelvic Organ Prolapse/Urinary Incontinence Sexual Functioning Questionnaire (PISQ-12)] and telephone interviews 1 year after surgery, the authors found that, after surgery, fewer women reported sexual interference from 'pelvic or vaginal symptoms', fear of incontinence, vaginal bulging and pain. More women were sexually active after surgery. The addition of Burch colposuspension did not have an adverse effect on sexual function. Dyspareunia after sacrospinous fixation procedure may be attributable to either vaginal narrowing, pudendal injury, deviation of the vagina or excessive colectomy during the concomitant repair procedure. The rates of postoperative dyspareunia are reported to be between 8% and 16% (Aslan et al 2005). Iliococcygeal fixation is another technique used to correct vault prolapse. In a matched case-control study comparing sacrospinous with iliococcygeal fixation, Maher et al (2004) found no significant difference in the percentage of women who were sexually active, or who had dyspareunia or buttock pain.

Meshes, both synthetic and biological, on their own or in the form of kits are used increasingly to reinforce vaginal

repairs, with the purpose of improving long-term results and preventing recurrences. However, there is very little information about their influence on sexual function. Following repair of large or recurrent anterior and posterior compartment prolapse using an overlay graft (atrium polypropylene), Dwyer and O'Reilly (2004) showed a decrease in dyspareunia over a 24-month period after surgery. In contrast, Milani et al (2005) found a 20% increase in dyspareunia after anterior repair and a 63% increase after posterior repair reinforced by mesh. Neither of these studies assessed other aspects of sexual function. More recently, Novi et al (2007) compared sexual function of women undergoing rectocele repair with porcine dermis graft with site-specific repair of the rectovaginal fascia using a validated questionnaire (PISQ), and found that subjects undergoing porcine dermis graft scored significantly higher on the PISQ 6 months after surgery. There is an urgent need for proper evaluation of meshes in all forms before they are widely used.

Historically, the uterus has been regarded as the regulator and controller of important physiological functions, a sexual organ, a source of energy and vitality, and a maintainer of youth and attractiveness. It is logical to hypothesize that removal of such an organ would lead to sexual problems. However, there is evidence to the contrary. The largest prospective study to date is the Maryland Women's Health Study (Rhodes et al 1999), which enrolled 1299 women who were interviewed with validated questionnaires before and 6, 12, 18 and 24 months after hysterectomy for benign conditions. They found a significant increase in frequency of sexual activity, a decreased rate of frequent dyspareunia, a decrease in reduced orgasm and a reduction in low libido rates. The distribution of women not experiencing vaginal dryness improved significantly. Overall, this study found substantial improvements in sexual function after hysterectomy. An enduring debate in the late 1980s and the 1990s was whether subtotal hysterectomy might confer advantages over total hysterectomy with regard to sexual, urinary and bowel function, since the former entails minimal neuroanatomical disruption. However, a recent Cochrane review (Lethaby et al 2006) did not demonstrate any difference in pelvic organ dysfunction, quality of life and psychological function in women with and without conservation of the cervix 1 year after surgery, and this effect seems to persist on long-term follow-up (Thakar et al 2008). Roovers et al (2003), in a prospective, observational study over 6 months, found a reduction in sexual problems after vaginal, subtotal or total hysterectomy. However, the prevalence of one or more bothersome sexual problems 6 months after vaginal, subtotal or total hysterectomy was 43%, 41% and 39%, respectively, and new sexual problems developed in over 9% of cases. The authors acknowledged that the size of the study population might have been too small to detect slight differences.

Childbirth and puerperium

In the postpartum period, the combination of a new baby, fatigue, hormonal changes and a healing episiotomy scar may contribute to diminished frequency and enjoyment of sexual intercourse. Recent work on women's sexual health after childbirth has shown that sexual health problems are

common in this period. In a cross-sectional study of 796 primiparous women over a 6-month period after delivery, Barrett et al (2000) found that 32% had resumed intercourse within 6 weeks of birth and 89% had resumed intercourse within 6 months. Sexual health problems, as recalled by the women, increased significantly after childbirth, with 83% experiencing sexual problems in the first 3 months, which declined to 64% at 6 months, although not reaching the prepregnancy levels of 38%. Dyspareunia at 6 months post partum was significantly associated with a previous experience of dyspareunia and current breast feeding. In a further analysis of the same cohort of women, it was found that women who were depressed were less likely than women who were not depressed to have resumed sexual intercourse and to report sexual health problems at 6 months post partum (Morof et al 2003). However, sexual health problems were common after childbirth in both depressed and non-depressed women, and therefore the authors suggested that postnatal sexual morbidity cannot be assumed to be simply a product of depressed mental state. When the mode of delivery was analysed in this cohort of women, in comparison with vaginal delivery, the protective effect of caesarean section on sexual function was limited to the early postnatal period, primarily due to dyspareunia-related symptoms. At 6 months, differences in dyspareunia-related symptoms, sexual-response-related symptoms and postcoital problems between caesarean and vaginal delivery were much reduced or reversed, with none reaching statistical significance (Barrett et al 2005). van Brummen et al (2006) performed a prospective longitudinal study on 377 primiparous women using the Maudsley Marital Questionnaire to evaluate factors which determine sexual activity and sexual relationship 1 year after the first delivery. Not being sexually active in early pregnancy (up to 12 weeks of gestation), older maternal age at delivery and third/fourth degree anal sphincter tear were the main predictors of sexual inactivity and dissatisfaction with sexual relationship at 1 year post partum. Perineal trauma (second, third and fourth) and use of obstetric instrumentation were related to increased frequency and severity of dyspareunia at 6 months post partum.

Evaluation

Management of FSD begins with identification and diagnosis, and is based on the patient's self-report in conjunction with a clinical evaluation. It is important to make the environment conducive so that the patient feels at ease.

History

Presentation may be overt, wherein the woman presents with symptoms of lack of desire, orgasm and arousal, and/or pain. Sexual problems are often disguised and may present as unresolved complaints, requests for repeated investigations and multiple consultations, all of which should raise the suspicion of a hidden agenda. Removing the protective coat of the hidden agenda through listening, observing, feeling, interpretation and reflection of all the clues present in the consultation allows for its emergence

into the conscious. The hidden agenda of the patient needs to be acknowledged, the reason for the concealment needs to be respected, and the practitioner needs to provide an environment in which it can be expressed without fear. Thus, even taking a brief sexual history during a new patient visit is effective, and indicates to the patient that the discussion of sexual concerns is appropriate and a routine component of the consultation. For screening of sexual problems, simple questions are as effective as lengthy interviews and can be used in clinical settings (Roos et al 2009). Questions regarding the sexual problem should be asked to generate the full picture of current sexual response. The impact of the dysfunction on the patient's personal well-being and its significance should be quantified. In addition, the role of the partner, and the partner's sexual response and reaction to sexual problems should be ascertained where possible. As sexual functioning is multifactorial, a thorough medical, surgical, obstetric, gynaecological, psychiatric and social history should also be taken. History of cigarette smoking and alcohol and/or drug intake should be taken. Medications are an important part of the history, as many medications can have an adverse effect on sexual function. However, it should be noted that much of the available information is based on data from male subjects, and it is unknown whether dysfunctions noted in males will also exist in females. A history of sexual assault or trauma is a potential contributor to sexual and pelvic floor dysfunction.

With better understanding of the domains of female sexual function, there has been an increasing use of self-report questionnaires. The advantage of using these questionnaires, apart from the fact that they are valid and reliable measures of sexual function, is that they are easy to administer, relatively inexpensive and unobtrusive, and normative values are available for both clinical and non-clinical populations. Several generic questionnaires are available (e.g. the Brief Index for Sexual Function in Women, the Female Sexual Function Index and the Sexual Distress Scale). Recently, a condition-specific questionnaire has become available to evaluate sexual function in women with incontinence and prolapse — the PISQ. The PISQ was developed and validated in New Mexico in the USA. The PISQ has a long form and a short form. The long form contains 31 items, all with Likert scale responses, which are divided into three domains: behavioural-emotive (comprising 15 questions), physical (ten questions) and partner related (six questions). Higher PISQ scores indicate better sexual function (Rogers et al 2001b). The short form consists of 12 questions and is not divided into the three domains (Rogers et al 2003). The short form of the PISQ is useful in the clinical setting because it reduces the time and burden to the patient, and provides the clinician with objective means of evaluating functional outcomes of either medical or surgical interventions. In the research setting, the short form of the PISQ is useful when quality-of-life analysis is part of the armamentarium used to evaluate outcomes and compare results.

Other self-report measures, such as daily diaries and event logs, are also useful. These record sexual function variables such as the frequency of intercourse, quality of sexual encounter, satisfaction, medication use, etc. Diaries typically

require the subject to record sexual activity on a daily basis, whereas event logs are only completed on days when sexual activity occurs. The advantage of diary or event log measures is that they provide quantitative data regarding the frequency of sexual activity, and the proportion of successful attempts at intercourse or other forms of sexual activity. However, they are highly restricted in the scope of measurement, as they do not provide the broad multidimensional assessment of response afforded by self-administered questionnaires and are subject to response bias. However, despite these limitations, daily diaries and event logs have been recommended by regulatory agencies as primary endpoints for clinical trials in FSD.

Physical examination

A general physical examination, with specific attention to the vascular and neurological systems, should be carried out. In addition to blood pressure and peripheral pulses, general appearance should be assessed for secondary sex characteristics, hirsutism and signs of virilization. The genitalia and perineum should be examined in detail where a physical cause is suspected. This includes inspection for any developmental anomalies, signs of vaginal atrophy, warts, infections and scarring. Cotton bud evaluation of the external genitalia may confirm vestibular vulvitis and neuropathies. Signs of urinary incontinence should be elicited by asking the patient to cough with a full bladder. Gentle digital examination to elicit tenderness and scarring may be undertaken and, if tolerated, followed by bimanual examination to assess the condition of the cervix, uterus and adnexa. Any tenderness, swelling and thickening should be noted. If the patient complains of pain, it is important to try and reproduce the complaint. Episiotomy and previous surgical incisions may be sites of tenderness as a result of vaginal narrowing, scarring and nerve entrapment. The tone of the pelvic floor muscles should be assessed and any prolapse should be documented. At this time, the presence of vaginismus may also be noted as an involuntary contraction of the outer third of the vagina, which may be severe enough to preclude speculum examination. Speculum examination should reveal the condition of the vagina and cervix; where appropriate, bacteriological and chlamydia swabs can be taken. Sometimes, a rectal examination may be indicated with specific attention to the anal reflex.

Laboratory testing

Laboratory testing may be needed in some patients depending on the underlying condition, although no test can be recommended routinely. Standard serum biochemistry, full blood count and lipid profiles may identify vascular risk factors, such as hypercholesterolaemia, diabetes mellitus and renal disease. A measurement of serum thyroid-stimulating hormone may also be indicated if thyroid dysfunction is suspected. If menopausal status is uncertain, oestradiol, follicle-stimulating hormone and luteinizing hormone testing are recommended. The consensus of opinion is that analogue assays for free testosterone should not be recommended.

Specialized diagnostic testing

Diagnostic methods such as vaginal photoplethysmography, duplex Doppler ultrasonography, vaginal and clitoral temperature, and vibratory sensory testing, as well as selective pudendal arteriography increase the clinician's and patient's understanding of the pathophysiological mechanisms of sexual dysfunction, but lack of normative data limits the use of specialized testing.

Treatment

When an obvious underlying cause is found, this should be treated. Successful management of FSD entails understanding where the break occurred in the sexual response cycle. As there are multiple factors associated with dysfunction, the traditional medical illness model of cause and effect does not apply in FSD. Often a multidisciplinary, collaborative approach is needed. Referral to a psychotherapist should be considered when no organic cause is found, when the patient does not respond or is not satisfied with the primary intervention provided, or when the clinician feels that specialist intervention may offer the diagnosis and treatment that is most appropriate. Once a diagnostic evaluation is carried out, the patient's dysfunction can be accurately classified. It is important to identify to the patient any obvious reversible causes for FSD, or potential lifestyle changes that may be beneficial to sexual function, such as stopping smoking, eating a healthy diet, regular exercise, improving partner communication and stress reduction. In liaison with the general practitioner, it may be necessary to change medications which may affect sexual function.

Especially in the elderly, vaginal dryness may be alleviated by use of water-soluble lubricants. Although current evidence does not suggest a role of systemic oestrogen or oestrogen/progestin therapy in women with reduced desire, they have been used effectively in FSD related to genitourinary atrophy. Low-dose vaginal oestrogens are minimally absorbed and are associated with fewer side-effects than systemic therapy, and are therefore preferred. Currently available vaginal oestrogen products include vaginal oestrogen creams that are effective in low doses (0.5 g twice weekly) and a vaginal oestradiol tablet (twice weekly).

Most trials of testosterone replacement therapy have shown statistically significant improvement in sexual function and well-being in women who have undergone oophorectomy. Transdermal testosterone therapy in the form of a patch or gel, which delivers physiological doses, has shown positive impacts on sexual function domains in postmenopausal and surgically menopausal women with hypoactive sexual desire disorder receiving concomitant oestrogen therapy in a recent randomized trial (Kingsberg et al 2007). However, at present, there are no safety and efficacy data for testosterone supplementation in oestrogen-deficient women, with even less support for women who are not oestrogen deficient and who have intact ovaries. Furthermore, the adverse effects of long-term use are largely unknown, with most studies having a follow-up duration of

up to 2 years. Risks of androgen therapy include hirsutism, acne, adverse liver function and lipid profile changes, with a potential increase in insulin resistance and metabolic syndrome with long-term use. For surgically menopausal women who present with symptoms of reduced desire, low-dose testosterone can be started along with continuous oestrogen therapy. The response to treatment (both efficacy and side-effects) should be evaluated after 3–6 months. If the problem persists, the patient should be referred to a specialist clinic, or for relationship counselling, psychotherapy or lifestyle advice, as appropriate.

There are other agents in the experimental phase that deserve mention for their potential to improve symptoms. These include sildenafil (Viagra), L-arginine (a nitric oxide precursor), sublingual apomorphine (a dopamine agonist), prostaglandin E1 (applied topically to increase blood flow) and phentolamine (oral or vaginal application; an adrenergic receptor antagonist).

After vaginal delivery, the patient may experience persistent pain over the episiotomy or perineal trauma site. If localized tender scar tissue is identified, women can be advised to have sexual intercourse after application of lidocaine gel/ointment. If pain persists, perineal injections, consisting of a cocktail of 10 ml bupivacaine 0.5%, 1500 iu hyaluronidase and 1 ml Depo-Medrone, is injected into the site of maximal tenderness (Figure 60.3). Occasionally, a woman may present with a perineal skin web in the posterior fourchette or fusion of the labia. These can be divided after infiltrating the area with a local anaesthetic injection. In women who are breast feeding, dyspareunia may be due to vaginal dryness. New mothers could be alerted to this side-effect and given advice on the use of lubricants and oestrogen pessaries or creams if necessary, while being reassured about the benefits of breast feeding. In the absence of local pathology, if a psychosexual problem is suspected, referral to a psychosexual counsellor may be helpful (Thakar and Sultan 2007).

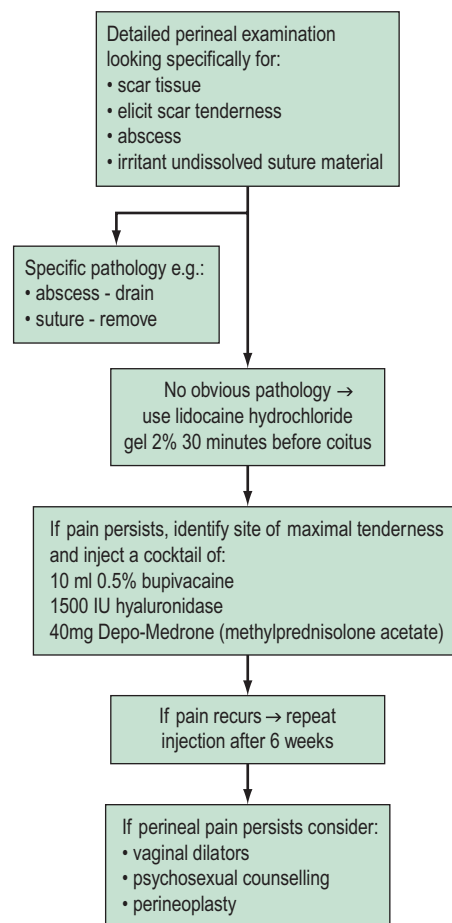

Figure 60.3 Suggested regime for management of perineal pain/dyspareunia.

KEY POINTS

1. Sexual dysfunction is a highly prevalent condition in women attending urogynaecological services.
2. Only a minority of urogynaecologists screen all patients for FSD.
3. Lack of time, uncertainty about therapeutic options and older age of the patient have been cited as potential reasons for failing to address sexual complaints as part of routine history.
4. Evidence from large prospective studies has shown that prolapse and/or incontinence have an adverse effect on sexual function.
5. Current evidence of the effect of conservative and surgical management of pelvic floor disorders on sexual function is encouraging.
6. Referral to a psychotherapist should be considered when no organic cause is found, when the patient does not respond or is not satisfied with the primary intervention provided, or when the clinician feels that specialist intervention may offer the diagnosis and treatment that is most appropriate.
7. While multiple tools are available for evaluation, assessment and therapy of FSD, a case-specific comprehensive and judicious approach works best.

Introduction

Chronic pelvic pain is recognized as a difficult or unsatisfactory area of clinical practice by both patients and doctors. Women report problems in communicating the impact of their longstanding symptoms to their gynaecologist, and clinicians trained in a surgical model of care may feel frustrated at their inability to rapidly identify a causal pathological process and institute curative therapy. This chapter aims to draw together current knowledge on the condition. While it would be impossible to attempt comprehensive elucidation of all the related subject areas, the aim is to present an overview which at least acknowledges the key elements of an integrative biopsychosocial approach to understanding the pathophysiology and management of the condition.

Biology of Pain

Pain is defined by the International Association for the Study of Pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage' (IASP Task Force on Taxonomy 1994). The emphasis in this definition is that pain is an experience rather than a neurophysiological process, and is therefore subjective. There is no such thing as 'objective' pain. This does not mean, however, that pain cannot be studied or that reproducible experimental models cannot be devised. Neuroscience has advanced knowledge of the biological processes underlying pain. It is no longer appropriate to discuss the subject in terms of 'pain pathways', by analogy with a wiring diagram, or even to consider that the nervous system conveys perceptions such as touch or pain. Rather, the elements of the nervous system, comprising the 'different fibres, tracts, pathways and nuclei process and convey information about bodily stimulus

events' (Berkley and Hubscher 1995). In this model, pain is a central nervous system construct derived from the totality of sensory input rather than from the activation of a particular pathway. Even the anatomy of neural pathways in the adult cannot be considered immutable; plasticity of the central nervous system has been clearly demonstrated in reproducible animal experimental models, such that a nerve injury leads to sprouting of afferent fibres within the dorsal horn of the spinal cord (Woolf et al 1992).

Special features of chronic and visceral pain

The processes underlying the transition from a single or repeated acute painful episode to a chronic pain state are of great potential clinical significance. Patients often relate the onset of their chronic condition to an event such as an acute infection or surgical procedure. Moreover, visceral sensory mechanisms differ in certain respects from those found in cutaneous tissues. Key mechanisms potentially underlying the transition from acute to chronic visceral pain states are the activation of silent afferents in viscera (McMahon 1997) and central sensitization (Woolf 1983). There are certain similarities but also important differences in the context of visceral sensation between central sensitization and wind-up, where the response to repeated C-fibre stimulation is progressively augmented (Herrero et al 2000). It had been hoped that the development of central sensitization and/or wind-up could be modulated by analgesics or other agents using a therapeutic strategy of pre-emptive analgesia (Dickenson 1997), although clinical applications of this concept have been disappointing.

Vascular pain and pelvic congestion

By analogy with the pathogenesis of cerebral migraine, it has been suggested that pain associated with pelvic congestion

might arise through vascular perturbation at the ovarian or uterine arteriolar level, resulting in the release of endothelial factors such as ATP which act by exciting sensory nerves in the outer muscle coat of venules and veins, and which also cause vasodilatation through the release of nitric oxide (Stones 2000).

Sex differences in pain

There is a marked sex difference in the prevalence of a number of chronic painful conditions unrelated to the reproductive tract in the general population, such as irritable bowel syndrome (IBS), temporomandibular dysfunction and interstitial cystitis, which has prompted research on the potential underlying mechanisms using animal models such as bladder irritation (Bon et al 1997), and uterine and vaginal distension (Bradshaw et al 1999). Illustrating the complexity of the central mechanisms underlying nociception, vaginal hyperalgesia resulting from induced endometriosis in rats was exacerbated in the presence of increased oestradiol levels, whereas in ovariectomized animals, hyperalgesia was relieved by oestradiol (Berkley et al 2007).

Studies of human volunteers have investigated pain thresholds in women at different stages of the menstrual cycle using electrical stimulation, pressure dolorimetry on the skin, thermal stimulation and induced ischaemic pain. Patterns of variation in response seen in studies using these modalities were different, and a meta-analytical review of pain perception across the menstrual cycle (Riley et al 1999) estimated the effect size for menstrual cycle fluctuation of pain sensitivity between the most and least sensitive phase to be 0.40. The effect size for sex difference was approximately 0.55, indicating that hormone variability could account for a substantial proportion but not all of the observed differences.

Illustrating some of the possible underlying mechanisms, a study of the discrimination of thermal pain in male and female volunteers showed that women had a lower pain threshold and tolerance, as also noted in a number of other studies (Fillingim et al 1998). A further complexity to be considered when interpreting studies of human volunteers is that subjects may well have prior pain experience which could influence responses to experimental pain (Fillingim et al 1999). Finally, the potential influence on pain perception of exogenous hormone therapy needs to be considered. In 87 postmenopausal women consulting for chronic orofacial pain, hormone replacement therapy (HRT) was associated with greater reported levels of pain, with substantial effect sizes between 0.39 and 0.62 (Wise et al 2000). The possibility of increased pain as a result of HRT use has not been addressed prospectively but may be clinically important, especially in women with vulval pain where oestrogen deficiency changes are thought to coexist.

Genetic variation in susceptibility to pain

There is now evidence for a genetic basis for the variation in response to pain seen in human experimental studies. Shabalina et al (2009) studied polymorphisms of the 'mu' opioid receptor OPRM1 gene locus, and reported a strong association between the single nucleotide polymorphism rs563649 and individual variations in pain perception.

There are also relevant observations from clinical populations with gynaecological pain; for example, a twin study showed that while 39% of the variance in reported menstrual flow was accounted for by genetic factors, the corresponding figure for dysmenorrhoea was 55% and for functional limitation from menstrual symptoms was 77% (Treloar et al 1998).

Epidemiology of Pelvic Pain: Populations, Consulting and Referral Patterns

The first assessment of the prevalence and economic burden associated with chronic pelvic pain was based on extrapolation from hospital practice in the UK, and estimated the prevalence in women at 24.4 per 1000. The annual direct treatment cost was estimated at £158 million, with indirect costs of £24 million (Davies et al 1992). The above prevalence now appears an underestimate since data from population-based studies have become available. A telephone survey was undertaken in the USA using a robust sampling methodology (Mathias et al 1996). Women aged 18–50 years were interviewed about pelvic-pain-related symptoms. In total, 17,927 households were contacted, 5325 women agreed to participate and 925 reported pelvic pain of at least 6 months' duration, including pain within the past 3 months. Following exclusion of pregnant and postmenopausal women and those with pain that was solely cycle related, 773/5263 (14.7%) were identified as suffering from chronic pelvic pain. Direct costs of health care, estimated from Medicare tariffs and hence very conservative, were \$881.5 million, patients' out-of-pocket expenses were estimated at \$1.9 billion and indirect costs due to time off work were estimated at \$555.3 million.

In the UK, the population perspective was provided by a postal survey of 2016 women selected at random from the Oxfordshire Health Authority register of 141,400 women aged 18–49 years (Zondervan et al 2001b). Chronic pelvic pain was defined as recurrent pain of at least 6 months' duration, unrelated to periods, intercourse or pregnancy. For the survey, a 'case' was defined as a woman with chronic pelvic pain in the previous 3 months, and on this basis the prevalence was 483/2016 (24.0%). Among those with pelvic pain, dysmenorrhoea was reported by 81% of those who had periods, and dyspareunia was reported by 41% of those who were sexually active. Among women who did not have chronic pelvic pain as defined above, dysmenorrhoea was reported by 58% of those who had periods, and dyspareunia was reported by 14% of those who were sexually active.

An estimate of the consulting pattern associated with pelvic pain was obtained using a national database study of UK general practices (Zondervan et al 1999b). Data relating to 284,162 women aged 12–70 years who had a general practice contact in 1991 were analysed to identify subsequent contacts over the following 5 years. The monthly prevalence rate was 21.5/1000 and the monthly incidence rate was 1.58/1000. These prevalence rates are comparable with those for migraine, back pain and asthma in primary care. Older women had higher monthly prevalence rates; for example, the rate was 18.2/1000 in women aged 15–20 years and 27.6/1000 in women over 60 years of age. This association is thought to be due to persistence of symptoms

in older women, with the median duration of symptoms being 13.7 months in 13–20 year olds and 20.2 months in women over 60 years of age (Zondervan et al 1999a). It is clear that future population-based studies need to include older women.

Among 483 women with chronic pelvic pain participating in the Oxfordshire population study discussed above, 195 (40.4%) had not sought a medical consultation, 127 (26.3%) reported a past consultation and 139 (28.8%) reported a recent consultation for pain (Zondervan et al 2001b). Of those women identified as cases of pelvic pain in the national general practice database, 28% were not given a specific diagnosis and 60% were not referred to hospital (Zondervan et al 1999a). The US population-based study discussed above also drew attention to the large numbers of women who have troublesome symptoms but do not seek medical attention: 75% of this sample had not seen a healthcare provider in the previous 3 months. It might be thought that not seeking care would be an indicator of milder symptoms; indeed, in the US study, those who did seek medical attention had higher pain and lower general health scores than those who did not seek medical attention. However, among those not seeking help, scores for pain and functional impairment were still substantial. Lack of use of medical services might reflect sociocultural factors, but could equally reflect previous unsatisfactory experiences of investigation and treatment, as discussed later in this chapter.

Among women referred to a UK gynaecology outpatient clinic with chronic pelvic pain of at least 6 months' duration, the impact of the condition on quality of life was assessed using the Short Form-36 (SF-36) questionnaire (Stones et al 2000). Figure 61.1 shows a comparison of physical and mental component summary scores derived from the eight SF-36 subscales (Jenkinson et al 1996a) in this hospital population with the data from the Oxfordshire population study described above. These summary scores are adjusted such that 50 represents a normal population mean. It will be noted that, as might be expected, the hospital sample is consistent with the trend, evident in those who have previously or recently sought medical advice compared with those who have not, to greater impairment of function on both physical and mental components.

Psychological Factors in Chronic Pelvic Pain

Many writers on pelvic pain have attempted to characterize an adverse psychological profile which might help the clinician to distinguish between 'organic' and 'psychogenic' pain; a distinction not in keeping with current neurophysiological understanding as discussed above. It is likely that some of the psychological disturbance that can be identified in women with chronic pelvic pain is the result of longstanding pain symptoms and unsatisfactory treatment, rather than the cause of pain (Slocumb et al 1989). Pain may contribute to or confirm a sense of helplessness or a tendency to engage in catastrophic thoughts, and may itself be exacerbated by them (Horn and Munafo 1997). On the other hand, it is clear that concomitant mood disturbance or specific psychopathology may impair the patient's ability to cope with her symptoms and contribute to functional impairment, and recognition is important but often neglected in the hurried

Figure 61.1 Means \pm 95% confidence interval for the Short Form-36 mental component and physical component summary scales. Women with pelvic pain (a) seen in a general gynaecology clinic (Stones et al 2000), or in a postal survey (Zondervan et al 2001b) reporting (b) a recent consultation, (c) a previous consultation or (d) no medical consultation. Arbitrary units such that 50 represents the mean of a normal population. From Stones RW, Selfe SA, Fransman S, Horn SA (2000) Psychosocial and economic impact of chronic pelvic pain. *Baillière's Clinical Obstetrics and Gynaecology* 14:27–43 and From Zondervan KT, Yudkin PL, Vessey MP et al (2001b) The community prevalence of chronic pelvic pain in women and associated illness behaviour. *British Journal of General Practice* 51(468):541–547.

setting of a gynaecology clinic (Yonkers and Chantilis 1995). The presence of adverse psychological propensities such as catastrophizing is a factor affecting outcome of treatment for chronic pelvic pain (Weijnenborg et al 2008).

Depression

Women presenting with multiple pain symptoms are at especially high risk for current mood disturbance; the likelihood of an associated mood disorder was increased six-fold in individuals with two pain complaints and eight-fold in those with three complaints (Dworkin et al 1990). In keeping with the irrelevance of the organic/psychogenic distinction for diagnosis, the absence of laparoscopically visible pathology was not associated with a higher probability of depression (Peveler et al 1995, Waller and Shaw 1995). In these studies, no differences in mood-related symptoms were identified in women with chronic pelvic pain with or without endometriosis. Antidepressant therapy may be indicated in order to alleviate depression, but sertraline was not effective for pelvic pain in a recent small but well-conducted randomized trial (Engel et al 1998).

Abuse and somatization

Child sexual or physical abuse may be an antecedent for chronic pelvic pain, but many individuals have suffered such abuse without this or other consequences in later life, and the research literature is beset with the problem of appropriate comparison groups. A study from a tertiary referral multi-disciplinary clinic setting reported on the full assessment of psychological factors in three groups of 30 women with chronic pelvic pain, chronic pain of other types, or without

pain identified from general practitioner records. Twelve (40%) of those with chronic pelvic pain reported sexual abuse, compared with five (17%) in each of the two comparison groups. Experience of physical violence was similar in the three groups, but women with chronic pelvic pain had higher scores for somatization, meaning the experience and communication of distress and physical symptoms without clear underlying pathology. In women with pelvic pain, abuse histories were evenly distributed among those with and without identified pelvic pathology such as endometriosis, but somatization scores were higher among those with identified pathology (Collett et al 1998). It has been suggested that the potential link between sexual abuse and pelvic pain might be that abuse is an observable marker for childhood neglect in general (Fry et al 1997), and this might explain the association in some studies with physical rather than sexual abuse (Rapkin et al 1990). With regard to mediators between abuse and pain experience, those who reported abuse were more likely to be distressed and anxious (Poleshuck et al 2005).

Identification of patients with features suggesting somatization disorder is important as failure to do so will lead to further inappropriate investigation, and treatment directed towards physical symptoms which are, in fact, manifestations of psychological distress. There are limited data regarding the prevalence of frank somatization disorder in clinic populations; in a study comparing the medical assessment with a standardized questionnaire, doctors identified 19% of patients as being potential somatizers, and approximately 5% met questionnaire criteria for overt somatization disorder (Peveler et al 1997). With regard to patients within the pelvic pain spectrum of conditions, the finding of Zolnoun et al (2008) of higher scores for somatization among patients with primary vulval vestibulitis compared with those with secondary vulval vestibulitis indicates a need for more detailed characterization of this propensity among the different clinical subpopulations.

Sociocultural Factors in Chronic Pelvic Pain

It could be argued that in life-threatening medical conditions or conditions where a technical solution gives excellent results, the patient's experience of care and the quality of doctor-patient communication are not critical to the outcome. In contrast, in ill-defined, chronic conditions where a technical solution is unlikely to provide relief, sociocultural factors have a major influence on the patient's decision to seek care and the referral pathway subsequently followed. The population-based studies cited above provide an indication of the size of the iceberg of symptoms below the waterline of care seeking. Similarly, in general practice, many women remain undiagnosed and unreferred. This is not necessarily inappropriate but the determinants of presentation and referral are unlikely to be disease factors alone. Once seen in a gynaecology clinic, the interaction between disease states and the consultation setting can be identified in statistical models; the presence of endometriosis was a factor predicting continuing pain 6 months after an initial hospital outpatient consultation, but so also were the patient's initial report of pain interfering with exercise, her rating of the initial medical consultation

Figure 61.2 Fitted probabilities of complete pain resolution with and without exercise impairment in relation to the patient's rating of the initial hospital consultation. In women without exercise impairment, a favourable rating of the initial consultation is associated with a higher probability of pain resolution, but the consultation has no effect in those with impairment. From Selfe SA, Matthews Z, Stones RW (1998) Factors influencing outcome in consultations for chronic pelvic pain. *Journal of Women's Health* 7:1041–1048.

as less satisfactory (Figure 61.2) and the individual clinician undertaking the consultation (but not the doctor's grade or gender) (Selfe et al 1998a). The ability to establish a therapeutic rapport and meet the patient's expectations during consultations, rather than simply convey information, may be factors that favour a good outcome (Stones et al 2006).

These statistical observations are consistent with women's descriptions of their experiences during the referral and treatment process. Sometimes, news of the absence of specific pathology at laparoscopy is received not as reassurance but as a dismissal. The patient's loss of confidence is expressed in these words obtained during focus group interviews:

Well — I suppose they must have done their job but they said to me that I probably had endometriosis and I felt all my symptoms related to that and that's what it was going to be — it seems strange that they don't actually find anything but obviously they're looking and they know what they can see ...

Often, problems are encountered not just with a particular individual clinician or aspect of care, but tend to accumulate for some patients as they move through the system. This seems to be more of a problem for women of low socioeconomic status (Grace 1995). A solution to this mismatch between women's needs and the structures through which care is provided may be the multidisciplinary approach, which at least works against the crude compartmentalized organic/psychological causation model, although it has been suggested that a more fundamental reconsideration of the medical paradigm is required (Grace 1998). Meanwhile, within the practical constraints of time, lack of continuity of care in the hospital setting and very limited access to multidisciplinary resources, gynaecologists can at least recognize the potential impact of their own attitudes and communication styles (Selfe et al 1998b).

Clinical Assessment

The conventional gynaecological history needs to be supplemented by additional information in consultations for chronic pelvic pain to aid understanding of the impact of symptoms and diagnosis.

Pain history

The history needs to include the onset and duration of symptoms, the location and radiation of pain, factors associated with exacerbation and relief, and the relationship of pain to the menstrual cycle. Dysmenorrhoea may be a separate or related symptom. Dyspareunia may include pain during intercourse but, for many women, a particularly unpleasant symptom is postcoital pain; specific enquiry should be made about this.

A number of validated pain assessment measures are available for use in research and clinical practice, the most convenient of which are the 10 cm visual analogue scale, the Brief Pain Inventory (BPI) and the McGill Short Form pain questionnaire. The McGill questionnaire is included in the International Pelvic Pain Society's assessment form, available for downloading at www.pelvicpain.org; the BPI may be downloaded at mdanderson.org/departments/PRG/. Patients' recall of pain symptoms over the previous month seems to be adequate, and it is probably unnecessary to ask for a daily pain diary: 10 cm visual analogue scales for 'usual' and 'most severe' intensity of pain recalled over the past 4 weeks correlated very well with mean and maximal diary records (Figure 61.3) (Stones et al 2001).

Impact on quality of life

At present, a validated illness-specific instrument is not available for assessing quality of life and functional impairment

Figure 61.3 Visual analogue pain scores (circles) from a daily pain diary completed over 8 weeks by a patient undergoing treatment as part of a clinical trial. Vertical bars show the recalled 'usual' (lower end of bars) and 'most severe' (upper end of bars) pain scores from the previous 4 weeks. Shaded columns areas show days of menstruation and filled circles indicate days when intercourse occurred. VAS, visual analogue scale.

in women with pelvic pain. Simple questions about the effect of the pain on work, leisure, sleep and sexual relationships are nevertheless useful. A generic quality of life measure such as the SF-36 may be used for monitoring outcomes. The SF-36 is somewhat problematic when used in episodic conditions such as menorrhagia (Jenkinson et al 1996b), but has face validity and reliability in chronic pelvic pain (Stones et al 2000).

Sexual and physical abuse

The extent to which clinicians can or should attempt to elicit a history of sexual or physical abuse during a gynaecological consultation is a matter for judgement in relation to the setting, in particular the follow-up and support that are available to women following such disclosure. The history may be volunteered unprompted by the patient, particularly during a subsequent consultation when rapport has been established. Some women may even find it easier to raise the subject with an unfamiliar specialist than with a general practitioner with whom they have regular consultations for other matters. It may be useful to incorporate questions on abuse into a self-completion questionnaire, such as that provided by the International Pelvic Pain Society, or in a multi-disciplinary clinic to address the topic during a consultation with the nurse or psychologist (see Chapter 65 for more information).

Systems review

The history should be thorough with regards to symptoms potentially indicative of IBS; the poor outcome of patients with IBS referred to gynaecology clinics has been emphasized (Prior and Whorwell 1989). It is unlikely that dyspareunia can be attributed to IBS; bowel spasm perhaps accounts for the experience of those patients who describe an interval between the end of intercourse and the onset of acute pain (Whorwell 1995) associated with the urge to defaecate and abdominal distension. Pain associated with micturition or a full bladder should be enquired about, as there may be some overlap between chronic pelvic pain and the interstitial cystitis spectrum discussed in Chapter 56.

Physical examination

Observing the patient as she walks may give an indication of a musculoskeletal problem, and examination of the back is relevant in those giving a history of pain radiating or originating in this area. Abdominal examination may reveal specific sites of tenderness. One-finger 'trigger point' tenderness will suggest a nerve entrapment, often involving the ilioinguinal or iliohypogastric nerves. These can develop spontaneously as well as following surgery. The diagnosis is confirmed after obtaining appropriate consent by infiltration of local anaesthetic into the tender area. 'Ovarian point' tenderness has been described as a feature of pelvic congestion syndrome (Beard et al 1988), but this sign is problematic in patients with IBS who often have similar abdominal tenderness. A general neurological examination is appropriate to exclude a systemic neuropathy or demyelination; if abnormalities are present, a neurology opinion should be sought.

Vaginal examination should commence with a careful inspection of the vulva and introitus, paying particular attention to the presence of erythema which might suggest primary vulval vestibulitis (Gibbons 1998) (see Chapter 40). More frequently, no erythema is evident but a gentle touch with a cotton-tipped swab in the area just external to the hymeneal ring elicits intense sharp pain, even in patients who do not complain of dyspareunia. This allodynia in the absence of visible erythema probably represents referred sensation from painful areas higher in the pelvis, but represents the primary problem for some women. Vulval varices may indicate incompetence of valves in the pelvic venous circulation; this subgroup of patients may benefit from radiological assessment and treatment (see below).

A gentle one-finger digital examination commences with palpation of the pelvic floor muscles. Focal tenderness may be present, indicating a primary musculoskeletal problem that should prompt referral to a pelvic floor physiotherapist for further assessment. As with 'vestibulitis', pelvic muscle tenderness may be a residual secondary response to pain from other parts of the pelvis; for example, a previous episode of pelvic infection. Further digital examination may reveal nodularity in the pouch of Douglas or restricted uterine mobility suggestive of endometriosis. Adenomyosis may be suggested by a bulky tender uterus. Uterine retroversion should be noted, although its relevance to dyspareunia is debatable. Adnexal rather than uterine tenderness may point to pelvic congestion syndrome. In the UK clinic setting, pelvic tenderness is unlikely to indicate chronic pelvic inflammatory disease (PID), although this diagnosis will be more likely among populations where early and appropriate antibiotic treatment for acute pelvic sepsis is less readily given.

Investigations

It is helpful to discount active pelvic infection, especially the presence of chlamydia, early in the assessment by taking endocervical swabs. Ultrasound examination may be useful in identifying uterine or adnexal pathology. The presence of dilated veins may indicate pelvic congestion (Stones et al 1990), but a recent study using power Doppler suggested that the primary value of sonography was to identify the characteristic multicystic ovarian morphology seen in this condition (Halligan et al 2000). Transuterine venography is of limited value in routine clinical practice, but is technically simpler than selective catheterization of the ovarian vein. Magnetic resonance imaging provides the opportunity to identify adenomyosis but is not indicated routinely.

Laparoscopy is commonly undertaken as the primary investigation for chronic pelvic pain in many countries. The aim of laparoscopy is to aid diagnosis but also, increasingly, to provide 'one-stop' treatment for endometriosis and adhesions where these are identified. This approach is cost-effective for endometriosis treatment, as the expense of a second procedure or hormonal treatment is obviated (Stones and Thomas 1995). However, given the potential for confusion arising from a 'negative' laparoscopy (Howard 1996) and the lack of a clear impact of recourse to laparoscopy on outcome at the referral population level (Peters et al 1991, Selfe et al 1998b), arguments in favour of deferring laparos-

copy, at least until initial symptomatic treatment has failed, take on some force. The impetus for treatment using gonadotrophin-releasing hormone (GnRH) agonists without laparoscopic diagnosis has emanated from the US-managed care environment (Winkel 1999), and from retrospective assessment of outcomes in the UK (Lyall et al 1999). For clinical practice, the timing of laparoscopy is a matter for discussion with the patient based on her needs for diagnosis and treatment, and the overall context of treatment modalities available.

Pain mapping by laparoscopy under conscious sedation can be a useful procedure, particularly where the site of pain is unilateral, allowing comparison with a 'control' area to assess the significance of adhesions, to identify unrecognized occult inguinal or femoral hernias, and in the negative sense to identify individuals with a generalized hyperalgesic chronic pain state for whom further surgical intervention would be hazardous. The choice of instrumentation represents a trade-off between the lower quality field of view available from a 2 mm laparoscope and patient discomfort associated with a larger trocar and cannula. In practice, a 5 mm laparoscope does not cause significantly more pain than the smaller instruments. Following early reports of experience (Howard 1999), there are indications that clinical outcomes can be improved for some patients where conventional approaches have not proved successful and the laparoscopic findings have been unclear (Swanton et al 2006).

Diagnosis and Treatment: Specific Conditions

There is limited evidence from randomized clinical trials on which to base treatment decisions for women with chronic pelvic pain (Stones et al 2005). An approach to specific conditions is outlined below.

Pelvic congestion syndrome

This condition may be considered a clinical syndrome based on the characteristic symptom complex described by Beard et al (1988). Pelvic congestion is typically a condition of the reproductive years and, in contrast to endometriosis, is equally prevalent among parous and nulliparous women. There may be an underlying endocrine dysfunction, although peripheral hormone levels are not abnormal. The associated ovarian morphology is characterized by predominantly atretic follicles scattered throughout the stroma, while in contrast to polycystic ovary syndrome, the volume of the ovary is normal. The thecal androstenedione response to luteinizing hormone was increased as in polycystic ovaries, but granulosa cell oestradiol production was reduced compared with normal tissue (Gilling-Smith et al 2000).

Symptoms include exacerbation of pain with prolonged standing, dyspareunia, postcoital aching and a fluctuating localization of pain. Patients may derive reassurance from being given the diagnosis as an explanation of their pain in terms of a functional condition similar to cerebral migraine. Therapy includes identification of stressors and the use of hormonal treatment in combination with stress and pain management, with the aim of encouraging the patient to make appropriate lifestyle changes so that her symptoms are less likely to recur on completion of a course of hormonal

treatment. Medroxyprogesterone acetate 50 mg daily has been shown to be effective (Farquhar et al 1989), and GnRH agonists with oestrogen 'add-back' are increasingly used in this indication although randomized trial data are lacking to date. Hysterectomy and bilateral salpingo-oophorectomy followed by long-term oestrogen replacement therapy is an option for those who have extreme symptoms partially or temporarily relieved by hormonal therapy, but this is naturally a treatment of last resort (Beard et al 1991).

Patients with peripheral venous disease and vulval varicosities are probably manifesting a different clinical entity from those described above. A surgical approach involving extraperitoneal dissection of the ovarian veins has been described (Hobbs 1976), and this group of patients may benefit from current interventional radiology techniques for vein occlusion (Figure 61.4). However, the evidence for useful benefit in those without vulval or lower limb varices is restricted to series where definition of the case mix is not always clear.

Endometriosis

Endometriosis is discussed in detail in Chapter 33. From the perspective of clinical practice in chronic pelvic pain, endometriosis presents special problems at both ends of the spectrum of disease severity. Women with endometriosis have poor outcomes compared with those with other conditions in terms of pain relief (Selfe et al 1998a), and they require careful attention to the provision of effective pain relief. Many women have undergone laparoscopy with the expectation of endometriosis being confirmed, and have difficulty coming to terms with the lack of a positive diagnosis when endometriosis is not found, as illustrated in the extract from a patient's comments presented above.

Treatments which suppress or ablate endometriosis are, in general, associated with relief of pain. In the case of hormonal therapies, a major benefit is the suppression of menstruation, resulting in the prevention of dysmenorrhoea. Laparoscopic surgical ablation of deposits in stage I–III disease is associated with reduction in pain, as demonstrated in the single available randomized trial (Sutton et al 1994), and laparoscopic surgery for endometriosis also improves pain symptoms, quality of life and sexual function (Abbott et al 2004). There are insufficient data to make clear recommendations about the different available surgical approaches (e.g. laser vaporization vs excision and diathermy) with respect to pain outcomes.

The place of laparoscopic uterine nerve ablation, as opposed to ablation of visible deposits, remains unclear. More positive results have been reported for presacral neurectomy in primary dysmenorrhoea (Chen et al 1996, Nezhat et al 1998), which perhaps reflects the greater potential for interrupting sensory pathways to the uterus offered by this procedure. There is significant surgical risk associated with presacral neurectomy, and an incidence of complications, especially constipation, and the importance of high-level surgical skills has been emphasized (Perry and Perez 1993). In the light of the discussion of pain mechanisms earlier in this chapter, efforts to achieve pain relief by interruption of nerve pathways are probably naïve as they do not take into account the central nervous system contribution to the maintenance of chronic pain states following an initial

inflammatory insult, of which endometriosis represents a good example.

Adhesions

Critical studies of the relationship between adhesions and pain suggest that they are often likely to be coincidental rather than causal (Rapkin 1986). Adhesiolysis by laparotomy was only effective for adhesions that were dense, vascularized or adherent to bowel (Peters et al 1992). Taking these findings together with those of Swank et al (2003) where laparoscopic treatment was employed, there is little evidence to support this approach (Stones et al 2005). As discussed above, pain mapping by laparoscopy under conscious sedation may be useful in identifying adhesions that are tender rather than asymptomatic, with due regard to the complexities of visceral sensory pathways previously reviewed and the sensitivity and discrimination of sensations from the pelvic organs under normal conditions (Koninckx and Renaer 1997). Laparoscopic adhesiolysis needs to be undertaken with particular care so as to avoid bowel injury, and with appropriate preoperative counselling and bowel preparation.

Chronic pelvic inflammatory disease

In UK clinical practice, chronic PID should be a laparoscopic diagnosis based on the finding of tubal damage and signs of active infection. The true prevalence will vary depending on the referral population, but a diagnosis based on a clinical impression of pelvic tenderness and partial response to repeated courses of antibiotics is likely to be incorrect. This observation is also relevant for regions with a higher background prevalence of PID such as sub-Saharan Africa (Kasule 1991). Apart from not resolving her problem, incorrect labelling of a patient as suffering from chronic PID may lead the patient to adopt an extremely negative self-image, and inflict on her inappropriate anxiety about future fertility.

Where the diagnosis is confirmed, surgery in the form of salpingectomy or salpingo-oophorectomy may well be indicated rather than conservative management. Efforts to prevent continuing pain from ovarian adhesions have included ovariopexy and the use of barrier films, but evidence in the literature of actual pain relief is scanty.

Nerve entrapment

The finding of abdominal wall tenderness which is consistently localized to a particular point should lead to consideration of a nerve entrapment. This predominantly involves the ilioinguinal and iliohypogastric nerves, the anatomy of which is illustrated in Figure 61.5, but genitofemoral nerve entrapment has also been described. A typical protocol for management includes establishing the diagnosis by infiltration of bupivacaine 0.25%, and demonstrating complete relief of pain and tenderness. This can be followed by one or two injections 1 month apart of bupivacaine and a long-acting corticosteroid such as Depo Medrone 40 mg. Surgical exploration and excision of the nerve can be undertaken with approximately 70% success (Hahn 1989, Lee and Dellon 2000). The response to an initial infiltration of bupivacaine is often much more prolonged than would be

Figure 61.4 Selective catheterization of the ovarian veins in a patient who presented with aching vulval varicosities which were successfully treated by embolization. (A) Transfemoral approach to the proximal left ovarian vein. (B) Distal left ovarian vein. Note dilatation and extensive communications to the uterine veins despite previous left oophorectomy. (C) Transjugular approach 2 months post embolization. Note occluded left ovarian vein. (D) Right ovarian vein showing residual collaterals. Note embolization coils visible on the patient's left.

expected from the duration of action of the local anaesthetic, perhaps because minor perineural adhesions are broken down by the volume of the infiltration, or surrounding muscle spasm is relieved.

Neuropathic and postsurgical pelvic pain

Whereas abdominal nerve-related pain can often be clearly localized to a particular site, posthysterectomy pain at the vaginal vault and vaginal pain following childbirth may be more difficult to evaluate. It is likely that the nerves involved are small unmyelinated fibres travelling in the nervi erigentes to the sacral segments and branches of the pudendal nerve. While nerve latency studies may be of value in assessing injury to the pudendal nerve, local anaesthetic nerve blockade is singularly unsuccessful. There may be the potential for surgery to decompress Alcock's canal where this is identified as the specific area of nerve compression, but case definition remains controversial.

In posthysterectomy pain, pain mapping may be useful to delineate the extent of tenderness at the vaginal vault, but this is usually with a view to aiding acceptance of a multi-disciplinary pain management approach to treatment including drugs such as gabapentin and cognitive-behavioural psychology (see below) rather than with an expectation of identifying a focal lesion amenable to surgery. Patients with more extensive neuropathy should be referred for a neurology opinion.

A special instance of postsurgical pain where further surgery is indicated is ovarian remnant syndrome, where a fragment of active ovarian tissue generates pain through continued ovulatory activity. The diagnosis can be made by withdrawing oestrogen replacement therapy and demonstrating endogenous hormone production, and the lesion can be localized by the administration of clomi-

phene or human menopausal gonadotropin prior to imaging. The surgery is technically challenging and is best approached by laparotomy rather than laparoscopy (Richlin and Rock 2001).

Hernias

Occult inguinal hernias have been recognized in women presenting with pain but without the normal swelling or cough impulse (Herrington 1975), but surgeons have naturally been reluctant to operate in the absence of more definite physical signs. Current surgical thinking on inguinal and femoral hernias, and rarities such as spigelian and obturator hernias, is reviewed by Daoud (1998). Inguinal and femoral hernias can readily be evaluated during pain mapping laparoscopy, as the anatomy can be easily visualized, localized tenderness can be detected, and laparoscopic repair can subsequently be undertaken.

Diagnostic overlap and 'no diagnosis'

Despite the best efforts of clinicians to identify specific causes of pelvic pain, it will be unclear how to classify many patients. In a consecutive series of 98 patients referred for investigation by their general practitioner, diagnoses were endometriosis ($n = 12$), adhesions ($n = 10$) and other gross pathology ($n = 15$). No positive diagnosis could be established in 29 patients. Three or more IBS symptoms were present in 15 patients, but there was overlap with other diagnoses in 13 of these patients. A symptom complex suggestive of pelvic congestion syndrome was present in 57 patients, but this overlapped with seven cases of endometriosis, six cases of adhesions, eight cases of gross pathology and nine cases of IBS (Selfe et al 1998b). Similar findings of no positive diagnosis and diagnostic overlap were noted in

women consulting in primary care (Zondervan et al 1999a), and self-reports of symptoms and received diagnoses in a population survey (Zondervan et al 2001a).

Management Settings and Strategies

The general approach to treatment of chronic pelvic pain needs to reflect the patient population and meet the different needs of individual women. Diagnostic and treatment plans need to be able to accommodate the spectrum of chronicity and severity of symptoms; it would probably be inappropriate to enrol every patient referred from general practice into a comprehensive multidisciplinary pain management programme, but it would be equally inappropriate to subject a patient who has undergone multiple previous investigations and treatments for longstanding disabling pain to a brief clinical encounter with an inconclusive outcome. If data from a UK hospital outpatient population can be regarded as typical, approximately 25% of women referred by general practitioners still had significant pain 6 months after an initial consultation; this may represent the scale of unmet need for a multidisciplinary service.

An important step in formulating a management plan for any patient is to establish her treatment goals, especially whether she is primarily concerned with identifying a cause for her pain or is less concerned with causation but desires rapid symptomatic relief. In the former instance, further investigation such as laparoscopy may help the patient towards her goal, whereas in the latter case, initial symptomatic treatment may be more appropriate. Further clarification may be required regarding the relative priority that the patient gives to pain relief and restoration of normal function. The impact of a well-conducted and sympathetic consultation may itself be therapeutic based on some of the research discussed above; indeed, ultrasonography has been used effectively as a means of providing reassurance (Ghaly 1994).

For patients at the more severe end of the illness spectrum, the elements of a pain management approach become more important; randomized trial evidence supports multidisciplinary care (Peters et al 1991). Multidisciplinary care may include contributions from other disciplines including anaesthesia, psychology, physiotherapy, nursing and liaison psychiatry. The analgesic regimen is optimized, bearing in mind that 6–10% of the Caucasian population are unable to metabolize codeine (Eckhardt et al 1998), and full use is made of adjunctive agents such as amitriptyline 10–50 mg at night or gabapentin in an incremental regimen from 400 to 3600 mg daily. The latter agent is indicated for neuropathic pain and does not interact with the oral contraceptive

pill, but has adverse effects of giddiness and drowsiness. Randomized trials have shown gabapentin to be of benefit for pain relief in diabetic neuropathy and trigeminal neuralgia (Backonja et al 1998, Rowbotham et al 1998).

Outcomes from non-randomized studies of multidisciplinary management in North Carolina were positive; 46% of 370 patients reported pain improvement after 1 year, with similar outcomes in those who had received primarily medical treatment (including psychological input) or primarily surgical treatment (Lamvu et al 2006). On the other hand, in Holland, 3-year follow-up of a cohort of 72 patients seen in a multidisciplinary clinic revealed a majority with continuing symptoms, pointing to the need for ongoing care for a chronic condition rather than a high expectation of cure (Weijnen et al 2007).

Regular scheduled follow-up is an important element of a pain management programme, as distinct from pain-contingent consultations, and every effort must be made to provide continuity of care. Transcutaneous electrical nerve stimulation (TENS) can be offered in appropriate circumstances and advice given on its correct use. The neurophysiological basis for TENS is that transmission of impulses via unmyelinated C fibres is inhibited at the level of the dorsal horn of the spinal cord by the activation of cutaneous myelinated afferents using electrical stimulation. Evidence from randomized trials suggests that while ineffective in labour pain and acute postsurgical pain, there may well be benefit in dysmenorrhoea. Formal trials of TENS in the context of chronic pelvic pain are lacking.

Where mood disturbance is identified, concomitant antidepressant therapy should be suggested. Where there are indications of more complex psychopathology, particularly somatoform disorder, a liaison psychiatry opinion is appropriate. The rate of attendance by gynaecological patients referred to psychiatric departments is extremely low, and there are considerable advantages to service models which enable cross-referral on the same premises at short notice; however, these often present practical problems. Psychological assessment itself has therapeutic value (Price and Blake 1999), and a psychologist or psychotherapist can provide guidance on pain and/or stress management and motivate patients to move from passivity to active participation in their treatment. Wherever possible, patients should be offered the opportunity of a structured programme of cognitive-behavioural therapy (CBT), as evidence for the benefit of this approach is strong. Taking the rigorous approach of identifying 'clinically significant change' as an endpoint for outcomes in a routine clinical setting, between one in three and one in seven patients seen in a UK chronic pain clinic experienced useful benefits from CBT (Morley et al 2008).

KEY POINTS

1. Pain is a central nervous system construct.
2. The organic/psychogenic categorization is obsolete.
3. The central nervous system exhibits plasticity.
4. Hormonal, sex and genetic factors influence pain perception.
5. Chronic visceral pain may involve activation of silent afferents and hyperalgesia.
6. Chronic pelvic pain is common among the general population and those consulting general practitioners.
7. Consultation rates are influenced by social class.
8. Mood disturbance and sequelae of abuse may be associated factors.

9. Women with multiple unexplained physical symptoms may have somatoform disorder.
10. Women with pelvic pain often find their experience of care unsatisfactory.
11. Pelvic congestion symptoms include dyspareunia and postcoital aching.
12. Pain mapping may be useful in the assessment of adhesions.
13. Chronic PID should only be diagnosed at laparoscopy and is uncommon in UK practice.
14. In many women, the diagnosis is unclear or diagnoses overlap.
15. Multidisciplinary care is more effective than standard care.
16. The model of care needs to meet the individual needs of women.
17. Experience of care can influence clinical outcome.
18. Ultrasonography can be used to provide reassurance.

PATHOGENESIS AND PATHOGENS	943	PREVENTION	950
DIAGNOSIS	944	KEY POINTS	952

Introduction

Pelvic inflammatory disease (PID) refers to ascending infection of the upper genital tract affecting the uterus (endometritis), fallopian tubes and ovaries (salpingitis, oophoritis, salpingo-oophoritis, tubo-ovarian abscess), and neighbouring structures. Although the definition of PID is precise, its diagnosis is not. The acute onset of clinical symptoms and signs aids the diagnosis of PID, but it is often subclinical and is only manifested through its long-term sequelae such as pelvic pain, dyspareunia, infertility or ectopic pregnancy.

The World Health Organization (WHO) guide to essential practice, 'Integrating STI/RTI Care for Reproductive Health: Sexually Transmitted and Other Reproductive Tract Infections', defined reproductive tract infections (RTIs) as a broad term that includes sexually transmitted infections (STIs) as well as other infections that are not sexually transmitted (World Health Organization 2005). Not all STIs are RTIs, a reference to the location of the infection, and not all RTIs are STIs. In most instances, STIs have much more severe health consequences than other RTIs, and the terms 'STI' and 'RTI' are often used together to highlight the importance of STIs within RTIs.

This chapter will address PID as an upper genital tract infection that may be caused by organisms normally present in the reproductive tract (endogenous), or introduced from the outside during sexual contact (STI) or medical procedures (iatrogenic), and will outline its consequences and management as well as wider global prevention. Readers are also referred to Chapter 63 on non-HIV STIs.

Epidemiology

Epidemiological studies of PID are adversely affected by diagnostic and reporting uncertainties. The symptoms are often subtle and mild, and it is common that many cases of PID are missed because women or healthcare professionals

fail to recognize mild or non-specific symptoms and their implications. As there are no simple, safe and specific diagnostic tests for PID, Simms et al (2003) proposed that it was time to rethink its diagnosis.

To complicate matters, adolescent and young adult women are reported to have anxiety surrounding pelvic examination (Millstein et al 1984), and in another study, over half of teens screened for STIs by urine testing and pelvic examination preferred the urine screening (Serlin et al 2002) for evaluating genitourinary (GU) symptoms without undergoing a speculum examination. Such new approaches may encourage young women who fear or otherwise avoid pelvic examinations to receive more timely evaluation, and could also result in access to diagnostic services in settings that do not currently provide them, such as school-based health centres, community centres and detention facilities, enabling clinicians to diagnose and treat many high-risk youth whose infections might otherwise go undetected (Burstein et al 1998, Pack et al 2000).

Estimates of prevalence

STI clinics are commonly viewed as the source for determining the prevalence and incidence of PID. However, an individual's attempt to seek medical advice following risk exposure is dependent on the individual's perception of risk, level of concern, tendency to utilize such clinics, development of symptoms or fear of transmitting infection to their sexual partner. Furthermore, to determine the true prevalence or incidence, it is essential to have a clearly defined base population, be it 'at-risk' or 'general'; something that is inherently difficult and very complex.

Adolescent and young adult women account for nearly half of over 1 million cases of PID reported annually in the USA (Washington and Katz 1991). Chlamydia infection is the most common bacterial STI in the USA, with more than 2.8 million new cases estimated to occur each year (Weinstock et al 2004); this is the most common cause of PID.

During 2007, approximately 1.1 million cases of chlamydia were reported to the Centers for Disease Control and Prevention (CDC); more than half of these were in females aged 15–25 years (Centers for Disease Control and Prevention 2009a). The annual incidence and prevalence of STIs is difficult to calculate. The incidence of STIs may be estimated on the bases of nationally notifiable diseases, national surveys, WHO reports and medical literature in this area. There is almost certainly under reporting due to the frequently asymptomatic nature of the disease, and the true annual incidence and prevalence are very likely to be much higher. A recent trend in developed countries highlights a shift in the microbial aetiology of PID, with an increasing role of chlamydia and a decreased role of gonococcal infection (van der Heyden et al 2000). Similarly, PID is now a disease that is mainly diagnosed in primary care or other similar outpatient environments. Since the advent of sensitive molecular amplification tests that permit non-invasive diagnosis of chlamydia, epidemiological evidence suggests that the proportion of chlamydial PID is increasing compared with other causative agents (Hughes et al 2001). There is also evidence that a significant number of chlamydial infections are asymptomatic, which allows silent cross-infection, and if untreated remains infectious in male and female hosts for months. Joyner et al (2002) demonstrated the persistence of chlamydia in 87% of men and women. WHO estimated 89 million new cases of genital chlamydial infections worldwide in 1995 and 92 million in 1999 (Peeling et al 1998, World Health Organization 2001).

In the UK, STI surveillance systems are based on data from GU medicine clinics and laboratory reports submitted to the Health Protection Agency Centre for Infections. However, this does not take into account the substantial number of relatively asymptomatic STIs that are diagnosed and treated in primary care settings. Simms et al (2006) examined the strengths and weaknesses of the Royal College of General Practitioners' (RCOG) Weekly Returns Service to determine the incidence of a range of STIs and associated clinical conditions. In their study, data were collated from 78 sentinel general practices in England and Wales between 1994 and 2001, covering a population of approximately 600,000. The authors reported that candidiasis was the most common condition reported in both men and women, followed by PID in women. The mean annual incidences per 100,000 women between 15 and 44 years of age were as follows: PID, 1787; vaginal discharge, 285; non-specific urethritis, 8.2; candidiasis, 4218; *Trichomonas vaginalis*, 28; genital herpes, 127; and genital warts, 184. Interestingly, the incidence of candidiasis and PID declined over this period in all groups, while the incidence of vaginal discharge doubled in 15–24 year olds over the same period. This decline in the incidence of PID is in marked contrast with the 148% increase in the diagnosis of chlamydial infections made in GU medicine clinics in the same period. The increase in diagnosis may have been brought about by an increase in case ascertainment, the increased availability of diagnostic facilities and an increase in disease incidence, while the decrease in PID probably reflects improved diagnosis and management of the syndrome. The aim of the National Chlamydia Screening Programme (NCSP) since its introduction in England in 2003 has been to control the infection through early detection and treatment of asymptomatic individuals. More than

one and a half million (1,673,276) tests were performed on 15–24 year olds by the NCSP between 2003 and the end of July 2009, and a further 376,966 non-NCSP, non-GU medicine tests were reported. Interestingly, the test-positive rate has declined steadily for both men and women since the programme started. The average test-positive rates for screened women and men were 8.38% and 6.78% for 2008–2009, and 7% and 6.3% for the first quarter of 2009–2010, respectively. In both durations, the highest rates were found in women aged 16–19 years and men aged 20–24 years (Figure 62.1). Other risk groups were those reporting behavioural risk factors and certain ethnic groups (National Chlamydia Screening Programme 2009).

Pathogenesis and Pathogens

The main causative agent of PID in the UK is *Chlamydia trachomatis*. Other less common causes include gonorrhoea, mycoplasma, gardnerella and Gram-negative rods (British

Figure 62.1 Proportion of positive cases of chlamydia by age and sex in England. (A) April 2008–March 2009. (B) April–June 2009.

Association for Sexual Health and HIV 2005). *Trichomonas vaginalis* appears to have little, if any, role in the aetiology of PID. Bacterial vaginosis has been associated with PID, and the presence of bacterial vaginosis and leukocytes on vaginal slides is associated with a five-fold risk of PID (von Knorring and Wilson 2007). Other pathogens that should be considered, especially in immigrant women, include tuberculosis and schistosoma. Pelvic and genital tuberculosis is a blood-borne infection. Schistosoma infection should be considered in cases of granulomatous salpingitis (Kameh et al 2004). Actinomycosis is another causative agent of PID, and is often associated with intrauterine contraceptive device (IUCD) use.

Chlamydia

Chlamydia is a Gram-negative obligate intracellular parasite that can cause a variety of disease manifestations in humans. Chlamydia can be defined into different species depending upon its biochemical properties, although molecular analysis has led to further reclassification. In humans, serovars A–C cause conjunctivitis and resultant trachoma, whilst serovars D–K cause urethritis, cervicitis, ophthalmia neonatorum and neonatal pneumonia. LGV serovars produce a specific STI called lymphogranuloma venereum. Chlamydia has many features that are similar to a bacterium. It possesses a cell wall, hence it is sensitive towards penicillin, has the capacity to reproduce RNA and DNA, and is treatable with antibiotics. Unlike bacteria but like viruses, it must infect a host cell to reproduce. These characteristics initially made research difficult, but the application of genetic amplification tests resolved this problem. Chlamydia has a great affinity to adhere to the columnar epithelial cells of the endocervical canal, and also the epithelial cells of the endometrium and fallopian tube. Chlamydia is highly infectious in its extracellular state and consists of particles 0.2–0.4 µm in diameter, known as ‘elementary bodies’. These elementary bodies enter the cell via phagocytosis, but have the capacity to avoid immunological destruction by inhibiting fusion with lysosomes. Over the following 24 h, the elementary bodies expand into larger reticulate bodies. These bodies rapidly divide by a process of binary fission to create several intracellular inclusion bodies, each of which is crammed with thousands of new reticulate bodies. These reticulate bodies condense to form new elementary bodies to complete the replication cycle, and upon lysis of the infected cell, thousands of new highly infectious elementary bodies are released. Host cell destruction is, of course, a byproduct of the replication process, but this is not enough tissue damage to explain the significant upper genital tract damage that occurs with chlamydial infection. This is likely to be due to the host humoral and cell-mediated immune response to infection, and would explain the differences in the effect of the host genetics upon the degree of clinical infection and the long-term sequelae. It is interesting to note that primary infection of chlamydia in monkeys in self-limiting but repeat exposure results in tubal damage, supporting a delayed immune response (Agrawal et al 2007).

Gonococcus

Gonococcal PID has decreased but is still a frequently encountered problem. Gonococcus, unlike chlamydia, is a

true bacterium with an incubation period of 2–14 days. On light microscopy it can be seen as a Gram-negative diplococcus. It has the capacity to adhere selectively to non-ciliated secretory cells, including those lining the fallopian tubes, thanks to its cellular pili. These are fine protoplasmic projections that allow attachment to host cells. It is believed that gonococcal infection produces an acute polymorphonuclear reaction, and this generates a toxin that damages fallopian tube ciliated cells. Males tend to present with symptoms, while it is asymptomatic in at least 60% of infected women. Gonococcal infection should be considered in women who present with PID and concurrent dermatitis or new arthritis; rarely, it results in septicaemia or concurrent pharyngitis.

Other agents

Aerobic and anaerobic agents are also often associated with PID, and are believed to be secondary agents that have the capacity to cause symptomatic infection after primary damage by chlamydia or gonococcus. Aerobic bacteria include staphylococcus, group B and D streptococcus, coliforms and *Haemophilus influenzae*. Pneumococcus has also been recorded to occur, and this is believed to be due to orogenital contact. The anaerobic group includes bacteroides, fusobacterium, peptococcus and a variety of clostridium species. Often, a mixed growth is cultured. Hence, it is important to treat both aerobic and anaerobic infections, and in the case of true tubo-ovarian abscess, the growth tends to consist mainly of anaerobes.

Source of entry

The majority of acute PID are ascending infections through the genital tract to the endocervix, which can act as a reservoir and spread to the endometrium and the peritoneal cavity via the fallopian tubes (Figure 62.2). There is evidence to suggest that the actual degree of symptoms and long-term complications of such infection are greatly dependent upon the type of infection and the host's immune response. Once infection has gained access to the peritoneal cavity, it can cause a significant inflammatory response including the formation of pus and resultant abscess formation, especially the destructive tubo-ovarian abscess. In addition, pathogens can cause periappendicitis, perisplenitis and perihepatitis. A well-known but inadequately studied phenomenon is the perihepatic adhesions of Fitz–Hughes–Curtis syndrome. It is believed that chlamydia and gonococcus act as primary pathogens disrupting the normal protective barriers of infection, which then allows the clinical infection of other secondary pathogens including endogenous microbes, causing a polyinfection, frequently with anaerobic involvement.

Diagnosis

Symptoms and signs

Even the most experienced reflective clinician may face a dilemma in making a diagnosis of PID, or feel concerned about over- or underdiagnosing PID, primarily due to the lack of good evidence-based diagnostic criteria compounded by its polymicrobial aetiology. Common PID symptoms are outlined in Box 62.1.

Figure 62.2 Pathogenesis of pelvic inflammatory disease (PID). PID begins with chlamydial and/or gonococcal cervicitis (A). This is followed by an alteration in the cervicovaginal microenvironment (B), leading to bacterial vaginosis (C). Finally, the original cervical pathogens, the flora causing vaginitis or both ascend into the upper genital tract (D). The grey shaded areas indicate the affected portions of the genital tract.

Modified from McCormack 1994 *New England Journal of Medicine* 330: 115–119.

The majority of women present with some but not all of these symptoms, which are not pathognomonic and account for the significant differences in determining PID rates among clinicians (Doxanakis et al 2008) and may result in failed treatments. In order to formulate an evidence-based approach to the diagnosis, several authors have attempted to generate a diagnostic scoring system to accept or refute the diagnosis of PID. A frequently used system is that published by Jacobson and Westrom (1969), whereby a diagnosis is made if acute lower abdominal/pelvic pain is accompanied by any two of the following features: abnormal vaginal bleeding, fever, vomiting, menstrual abnormalities, urinary symptoms, proctitis symptoms, marked pelvic tenderness, palpable mass or swelling, or erythrocyte sedimentation rate (ESR) >15 mm/h.

Although this is similar to the current guidelines of the RCOG, it remains a major concern that women with confirmed damaged fallopian tubes have no previous history of PID, mainly due to asymptomatic or atypical disease not being recognized (Sellors et al 1988). Munday's (2000) comprehensive review of the literature reported that many of the studies undertaken to estimate the accuracy of PID symptoms as a 'diagnostic test' had significant methodological flaws. Several used laparoscopy as a gold standard, which unfortunately may not be true, as it was reported to be of limited value with only 64% of suspected PID cases in one series being confirmed at laparoscopy (Sellors et al 1991).

Box 62.1 Symptoms and signs commonly associated with PID

- Bilateral lower abdominal tenderness (with occasional radiation to the legs)
- Abnormal vaginal or cervical discharge
- Fever ($>38^{\circ}\text{C}$)
- Abnormal vaginal bleeding (intermenstrual, postcoital or breakthrough)
- Deep dyspareunia
- Cervical motion tenderness on bimanual vaginal examination
- Adnexal tenderness or bimanual vaginal examination

Source: Royal College of Obstetricians and Gynaecologists 2009 Pelvic Inflammatory Disease. Green Top Guideline No. 32. RCOG Press, London.

Simms et al (2003) analysed the signs and symptoms of potential PID to generate likelihood ratios, and reported that abnormal vaginal bleeding, fever, vomiting, menstrual irregularity, ongoing bleeding, symptoms of urethritis, marked tenderness of pelvic organs on bimanual palpation, adnexal mass and ESR >15 mm in the first hour did not have significantly high sensitivity or specificity to be clinically valuable, and concluded that there was insufficient evidence to support existing diagnostic criteria for PID.

Current consensus suggests that the positive predictive value of a clinical diagnosis of PID is between 65% and 90%

when compared with laparoscopic findings, but this greatly depends upon the population studied (British Association for Sexual Health and HIV 2004). Adnexal tenderness has a particularly high sensitivity of 95%, but a very poor specificity of 22% (Peipert et al 2001).

The CDC factsheet (Centers for Disease Control and Prevention 2009b) indicates that the diagnosis is usually based on clinical findings, and if symptoms are present, a physical examination should be performed and further tests should be undertaken to identify the infection-causing organism. In view of the significant effects and long-term sequelae of untreated PID, it is wise to adopt a low threshold for treatment (Barrett and Taylor 2005) and to initiate early empirical treatment, although there is concern that this may lead to unnecessary treatment of women and there is no evidence to support or refute this strategy (Ross 2001a). With this in mind, clinicians should consider other risk assessments or investigations to improve diagnostic accuracy.

Risk assessment

Risk factors for STIs and PID are the same. In a longitudinal study, it was found that 39% of women with laparoscopically diagnosed PID were found to be infected with chlamydia and 14% with gonorrhoea (Bevan et al 1995). It is important to take a comprehensive sexual history from a patient with suspected PID. Risk factors include multiple sexual partners, lack of barrier contraception, young age and lower socioeconomic group. There is good evidence that anything that disrupts the cervical mucous barrier is a risk factor for PID. This includes uterine instrumentation, termination of pregnancy and insertion of an IUCD. There is significant evidence to support the fact that there are different levels of host susceptibility towards the development of PID, whereby polymorphism of mannose-binding lectin, an important component of the innate immune system and protector against chlamydial infection, may affect the extent of tubal damage in cases of chlamydial infection (Sziller et al 2008).

Evidence-Based Management

Investigations

Specific tests

Several tests may be employed for the diagnosis of PID, including microbiological swabs (endocervical, urinary, high and low vaginal swabs), inflammatory markers (C-reactive protein, ESR and differential white cell counts) and biophysical tests [transvaginal ultrasound scanning, Doppler scanning and magnetic resonance imaging (MRI) of the pelvis]. Microbiological tests remain the principal approach for the diagnosis of gonococcal and chlamydial infections, although the PID rate caused by the former is decreasing. Chlamydial tests have included cell culture, antibody tests and, more recently, nucleic acid amplification tests (NAAT), which allow greater accuracy at a relatively low cost. A recent meta-analysis suggested that pooled sensitivities for ligase chain reaction, polymerase chain reaction, gene probe and enzyme immunoassay of urine specimens were 96.5%,

85.6%, 92% and 38%, respectively, while on cervical swabs, the corresponding sensitivities were for PCR, gene probe and EIA 88.6%, 84% and 65%, respectively (Watson et al 2002). With any test, it is important to remember that the absence of lower genital tract infection does not exclude PID (Royal College of Obstetricians and Gynaecologists 2009).

Biochemical tests

Biochemical tests are often performed in suspected cases of PID. C-reactive protein is a non-specific acute phase inflammatory marker not normally found in serum. A cut-off value of 10 mg/l has a sensitivity of 93% and a specificity of 83% for acute PID. It responds more rapidly to therapy and thus is viewed as a better marker than ESR. C-reactive protein is also elevated in other infections, ovarian cyst accidents, ectopic pregnancies, malignancies, inflammatory bowel disease, appendicitis and endometriosis. ESR and differential white cell count are also non-specific and have a limited role in the diagnosis of PID.

Currently, it is recommended to perform endocervical swabs for chlamydia and gonorrhoea in suspected cases of PID (British Association for Sexual Health and HIV 2005). For chlamydia, NAAT performed on first-catch urine samples or vulvovaginal swabs are acceptable substitutes for endocervical swabs. Endocervical swabs for gonorrhoea should be sent in transport media and must arrive at the laboratory within 24 h. A positive NAAT for gonorrhoea should be confirmed by a positive culture test (British Association for Sexual Health and HIV 2005). Positive chlamydia and gonorrhoea tests (adjusted odds ratio 4.3, 95% confidence interval 2.89–2.63) are strongly associated with endometritis (Peipert et al 2001). Women with PID should be offered screening for other STIs (British Association for Sexual Health and HIV 2005).

A pregnancy test should also be performed to exclude ectopic pregnancy and to ensure that PID in pregnancy is treated promptly with inpatient management. It is also recommended to perform an urinalysis and urine culture to exclude urinary tract infection.

Imaging tests

Advances in medical imaging technology [ultrasound, computed tomography (CT), MRI] have renewed interest in their use for the diagnosis of PID.

Ultrasound scanning, especially transvaginal scan (TVS) (Figure 62.3), is particularly helpful in the diagnosis of tubo-ovarian abscess, where thick-walled, pus-filled, inflamed tubes may be demonstrated, and also in diagnosing other pathologies (e.g. ovarian cyst torsion, cyst accidents). TVS may also be beneficial in the diagnosis of acute appendicitis. Ultrasound in the acute diagnostic setting has not been subjected to the rigours of a clinical trial. Preliminary data on its use as a follow-up tool reported that of 86 women followed-up 3 months after confirmed acute PID, five developed a hydrosalpinx (Taipale et al 2003). TVS has become a first-line investigative tool in emergency gynaecology, and at least 10% of all referrals for TVS are for the investigation of acute pelvic pain. TVS allows rapid assessment of pelvic anatomy with greater accuracy and diagnostic detail compared with that of a bimanual examination. Abdominal

ultrasound can be used in cases of suspected appendicitis. Several other ultrasound features have been noted in cases of PID, including disruption of the normal pelvic anatomy, tenderness during TVS or the presence of free fluid in the pouch of Douglas. In a small study, the frequency of the ultrasound features of acute and chronic PID were assessed (Timor-Tritsch et al 1998). In the 14 patients with acute PID, a thickening of the fallopian wall was noted in all women, 12 demonstrated the 'cog wheel' sign and none of the patients demonstrated the 'beads on a string' sign. This was in marked contrast to women with chronic PID, where TVS could exclude other pathologies as well as distinguish between acute and chronic PID.

The addition of Doppler to grey-scale TVS may improve the sensitivity and specificity. Molander et al (2001) reported that an increase in the thickness of the fallopian tube walls was present in women with or without acute PID, but the application of Doppler ultrasound demonstrated the hyperaemia associated with acute PID. Pulsatility indices were significantly lower in women with acute PID compared with a control group. The use of power Doppler as a diagnostic

tool remains under investigation, and cannot yet be recommended to current practice. The application of percutaneous drainage with ultrasound imaging has been reported, but to date there have been no randomized controlled studies comparing percutaneous drainage with formal laparoscopic draining.

The evidence for the use of CT and MRI in suspected cases of acute PID is extremely limited, and their use is compounded by additional logistical problems and cost. CT imaging in PID may demonstrate thickening of the uterosacral ligaments, and the normally distinct pelvic floor fascial planes become obscured (Sam et al 2002). In more advanced disease, reactive inflammatory changes including large bowel ileus, hydroureter and even right upper quadrant inflammation consistent with Fitz-Hughes-Curtis syndrome may be noted. There is no comparative trial of CT in the diagnosis of PID. MRI has been compared with TVS and was reported to have greater sensitivity and specificity, but was limited by cost and accessibility (Tukeva et al 1999).

Laparoscopy

Diagnostic laparoscopy is often described as the diagnostic gold standard for PID; however, a negative laparoscopy does not exclude PID, and equally there is no evidence on the correlation between acute laparoscopic findings and the long-term sequelae of the disease. Its sensitivity is greatly dependent upon the diagnostic criteria used, and should be considered if there is a diagnostic dilemma or the presence of tubo-ovarian abscess is suspected. Features of PID seen at laparoscopy are shown in Figure 62.4.

Treatment

Treatment for suspected PID includes pain management, appropriate antibiotics, contact tracing, counselling and, occasionally, surgical intervention.

Outpatient care

Women with suspected mild-to-moderate PID can be effectively managed as an outpatient or within primary care provided that an ectopic pregnancy has been ruled out (Royal College of Obstetricians and Gynaecologists 2009). The Pelvic Inflammatory Disease Evaluation and Clinical Health (PEACH) randomized controlled trial ($n = 831$) reported that outpatient treatment of women with mild-to-moderate PID is as effective as inpatient treatment (Ness et al 2002). Short-term clinical and microbiological improvements were similar between the two groups, and after a mean follow-up period of 35 months, pregnancy rates were nearly equal (42.0% and 41.7%, respectively). There were also no differences in the time to pregnancy, chronic pelvic pain, ectopic pregnancy and recurrent PID rates between the two groups.

Inpatient care

Indications for hospital admission include severe symptoms and signs (nausea, vomiting and temperature $>38^{\circ}\text{C}$), signs of peritonitis, pregnancy, suspected tubo-ovarian abscess, 'unwell patient' or uncertain diagnosis, poor compliance with an outpatient regimen, and suspected perihepatitis.

Figure 62.3 (A) Transvaginal scan showing fallopian tube fimbrial and ampullary sections, loops of bowel and pouch of Douglas fluid collection. (B) Power Doppler transvaginal scan image of acute salpingitis. The thickened fallopian tube is entirely visualized because of surrounding pouch of Douglas fluid. Note hyperaemia associated with acute inflammation.

Figure 62.4 (A) Laparoscopic view of acute salpingitis. Note swollen hyperaemic fallopian tube next to a normal right ovary. The right tube has just been detached from the pelvic peritoneum. (B) Laparoscopic view of perihepatitis. Note perihepatic adhesions formed after chlamydial infection. The patient developed acute symptoms with severe pain in the right upper quadrant. (C) Laparoscopic view of severe pelvic inflammatory disease (PID). Note pyosalpinx formation with a phimotic fimbrial end. Normal ovary is visualized underneath the infected fallopian tube. (D) Laparoscopic view of severe PID. Note a unilateral left-sided tubo-ovarian abscess. (E) Laparoscopic view of severe PID. Note large bilateral pyosalpinx formation.

Women should be offered screening for other STIs before antibiotic treatment is started, although the latter must not be delayed. It is also recommended that women with suspected PID are referred to GU medicine for screening and effective contact tracing.

Analgesia

Analgesia should be started with ibuprofen or paracetamol; both should be combined if pain relief is unsatisfactory, or

one could consider adding codeine. If this is still unsatisfactory, it may be necessary to revise the diagnosis and treat as an inpatient (Ross 2001b). Drug interactions should be considered in women with medical problems such as epilepsy to avoid worsening of the primary illness.

Antibiotics

There is overall agreement that antibiotic therapy is appropriate for treating PID and conservative treatment cannot be

recommended, although there has never been a trial comparing placebo with any antibiotic treatment as this would now be unethical. Choice of antibiotic options are dependent on whether there is a high or low risk of gonococcal infection.

Box 62.2 outlines the appropriate antibiotic options for outpatient treatment of mild-to-moderate PID. It is important to inform the patient verbally and in writing that if she is using the combined contraceptive pill, patch or vaginal ring, additional conception is required for the duration of the antibiotic treatment and also for 7 days afterwards. It is also important to enquire about alcohol use before prescribing metronidazole. Patients should be informed that there is a potential risk of flushing, nausea, headache and dizziness if alcohol is taken with metronidazole. The incidence of this reaction is unknown, but it has been reported to occur between 0% and 100% (Baxter 2006). If the patient is unable to tolerate metronidazole, it may be stopped in cases of mild-to-moderate PID as the evidence to support its addition is extremely limited (Royal College of Obstetricians and Gynaecologists 2009).

Regimens containing ofloxacin or azithromycin are not recommended for cases with a high potential for gonococcal infection, as there appears to be increased prevalence of gonococcal resistance in the UK. A large multinational randomized double-blinded study compared the treatment of PID with moxifloxacin alone or with a combination of ofloxacin and metronidazole in women with no evidence of tubo-ovarian abscesses. This study concluded that both treatment options had similar efficacy, but moxifloxacin had fewer side-effects. However, moxifloxacin-resistant gonococci appear to exist (Ross et al 2006). In animal studies, ofloxacin may have associated side-effects and is not currently recommended to patients under 18 years of age (Royal College of Obstetricians and Gynaecologists 2009). Moxifloxacin is not licensed for the treatment of PID, and has been associated with an increased risk of life-threatening liver reaction (Medicines and Healthcare Products Regulatory Agency 2008).

There is better evidence to support the use of cefoxitin for the treatment of PID. However, it is often not widely available in the UK, and ceftriaxone is a suitable third-generation cephalosporin substitute. Patients treated with

doxycycline should be advised to avoid sunlamps or direct sunlight as there is a risk of photosensitivity reactions. A commonly used regimen for PID is still metronidazole and doxycycline, although there is no good evidence to support this, with a cure rate as low as 55% (Piyadigamage and Wilson 2005). In a systematic review of 39 studies, two trials evaluated treatment with metronidazole and doxycycline, and reported a clinical cure rate of 75% and a microbiological cure rate of 71% (Walker et al 1999). There is no evidence to support the use of a single dose of azithromycin alone, where better compliance might be an advantage (Bevan et al 2003).

PID in pregnancy

In early or potential early pregnancy, paracetamol is believed to be a safe analgesic, although the evidence for ibuprofen is weaker. The available evidence from the National Teratology Information Service has not noted any increase in congenital malformations before 30 weeks of gestation (National Teratology Information Service 2004). Current RCOG guidelines suggest that administering antibiotics in very early pregnancy is very unlikely to cause any fetal risks as significant drug toxicity would cause failed implantation. PID is very rare in later gestations. Tetracycline compounds should be avoided in pregnancy as they cause brown discoloration of the bone and teeth in fetuses exposed after 15 weeks of gestation, but this side-effect is not encountered with accidental exposure at earlier gestations (Schaefer et al 2007). Currently, the RCOG recommends treatment with cefotaxime, azithromycin and metronidazole for 14 days. No risk was associated with the use of metronidazole in pregnancy (National Teratology Information Service 2004), and no adverse effects were noted from the use of ceftriaxone on fetal development in animal studies. Similarly, azithromycin has very limited published data, but there does not seem to be an increase rate of fetal malformations following in-utero exposure.

PID and IUCDs

In women using an IUCD, it is appropriate to remove the device before treatment is started or if the symptoms have not resolved after 72 h. Clinicians should consider removing the IUCD in a patient with pelvic pain who has been noted to have actinomyces-like organisms previously. Where necessary, appropriate emergency contraception should be offered.

PID and HIV

In women with human immunodeficiency virus (HIV), treatment should be the same as for women without HIV (British Association for Sexual Health and HIV 2005). However, in clinically immunocompromised women or when there is failure to respond to standard treatment, advice from a HIV specialist team is recommended.

Compliance and partner screening

Women should be advised and counselled carefully about the implications of PID, the importance of compliance with treatment regimens, avoiding sexual intercourse until the

Box 62.2 Outpatient treatment for mild-to-moderate PID

Low-risk gonococcal infection

- Ofloxacin 400 mg orally twice daily and metronidazole 400 mg twice daily for 14 days.
- Ceftriaxone 250 mg as a single intramuscular dose plus oral doxycycline 100 mg twice daily and oral metronidazole 400 mg twice daily, both for 14 days.
- Ceftriaxone 250 mg as a single intramuscular dose followed by oral azithromycin 1 g per week for 2 weeks.

High-risk gonococcal infection

- Ceftriaxone 250 mg as a single intramuscular dose plus oral doxycycline 100 mg twice daily and oral metronidazole 400 mg twice daily, both for 14 days.

patient and her partner have completed the course of treatment to reduce the risk of reinfection, the advantages of screening for other STIs and the need for contact tracing. The patient may have to use barrier methods if intercourse is unavoidable (Royal College of Obstetricians and Gynaecologists 2009). Sexual partners within the preceding 6 months should be offered referral to a GU medicine clinic or be seen in primary care. The partner(s) should be tested for chlamydia, but empirical treatment would be recommended if this was not available. Gonorrhoea testing is only offered if the woman's or another partner's swab results are positive for gonococcus (Royal College of Obstetricians and Gynaecologists 2009).

Follow-up allows an assessment of compliance, encourages contact tracing, and is an opportunity to discuss the swab results, future prevention and health implications with patients. Acute PID managed on an outpatient basis should be reviewed within 72 h to assess the response and improvement of symptoms. If there is no benefit, it would be wise to consider reviewing the diagnosis and managing as an inpatient. Further follow-up may be arranged at 4 weeks to confirm that appropriate contact tracing has been carried out and to discuss PID implications. Generally, there is no need for further testing unless symptoms persist or there is a high risk of poor compliance.

Long-Term Societal and Global Health Impact

As indicated earlier, it is estimated that 8–10% of chlamydia infections and 8–20% of gonorrhoea infections progress to PID. In developing and low-resource communities, it is estimated that PID-related gynaecology admissions amount to 17–40% of all admissions in Africa, and 15–37% of all admissions in South-East Asia. After unsafe abortion, it is estimated that 10–23% of women with chlamydia and 15% of women with gonorrhoea will develop PID. This accounts for 7–29% of maternal deaths in developing regions. Equally, postpartum infection, which is rare with normal delivery if nothing is introduced into the vagina during labour, is up to 10 times more common in developing countries, accounting for up to 30% of maternal deaths (World Health Organization 2005).

A large ($n = 2501$) prospective cohort study between 1960 and 1984 reported an increase in infertility after PID (Westrom et al 1992). Sixteen percent of women with abnormal findings at laparoscopy (patients) and 2.7% of women with normal laparoscopy (control) failed to conceive. There was a higher rate of confirmed tubal factor in the women with abnormal findings at laparoscopy (10.8% and 0%, respectively). It was also noted that the incidence of tubal factor infertility increased with the number and severity of PID episodes. It was estimated that tubal factor infertility varied between 37% in developed countries and 85% in developing countries, which was very likely due to the effects of PID. Others have also reported a correlation between the severity of PID and the probability of infertility (Lepine et al 1998). After one episode of PID, the risk of infertility was estimated to be 15–25%, increasing to 50–60% after the third episode, and even higher rates where antibiotic treatment is not available. With this in mind, it is not surprising that there is a 10-fold increase in the incidence of ectopic

pregnancy (Westrom and Mardh 1983). In Africa, ectopic pregnancies occur in up to 32 per 1000 live births (World Health Organization 2005).

It is well established that communities with good access to effective prevention and treatment services have lower rates of STIs and associated complications. Thus, to broaden the benefits of prevention, active steps are required to overcome the challenges encountered in controlling STIs at community level by: (1) raising awareness; (2) promoting early use of clinic services and teaching people how to recognize symptoms and when to seek help; (3) promoting safer sexual practices when counselling clients (e.g. consistent use of condoms, fewer partners and delaying the age of first sexual intercourse); (4) detecting infections that are not obvious and screening for asymptomatic infection when possible; (5) preventing iatrogenic infection; (6) managing symptomatic STIs/RTIs effectively; and (7) counselling patients on staying uninfected after treatment.

Thailand demonstrated the success of prevention by greatly reducing the prevalence and transmission of common STIs/RTIs through addressing social and structural challenges. The incidence of the most common STIs was reduced by over 90% (Figure 62.5) through strong government commitment, the use of targeted strategies to reach the population where most STI transmission was taking place, better STI treatment and promoting increased use of condoms among commercial sex workers (World Health Organization 2005).

Chronic pelvic pain is common after acute PID and is often difficult to manage satisfactorily. Women with chronic pelvic pain after PID have a lower quality of life, may suffer work-related sequelae, are likely to experience adverse financial implications for treatment (Rein and Gift 2004), and frequently require operative interventions. It has been noted that hysterectomy and removal of adnexa is more common in women with a previous history of PID.

Prevention

Prevention of PID is most effectively achieved through avoiding exposure to STIs/RTIs, and endogenous or iatrogenic infections; equally, most of the serious health problems caused by STIs/RTIs are preventable. This section will assess options to prevent PID and its sequelae.

Prevention of sexually transmitted infections

Delaying sexual activity

Adolescents may come under significant peer pressure to become sexually active at an early age, when they are particularly vulnerable and at higher risk of STIs. Confidential support should be available for those who wish to delay sexual activity. Equally, adequate information should be available on safe sex, and prevention of STIs and pregnancy for those who decide to become sexually active.

Decreasing the number of sexual partners

Reducing the number of sexual partners reduces the risk of STIs and consequently PID. Partners in a longstanding monogamous relationship have an extremely low risk of

Figure 62.5 Reported cases of sexually transmitted infection (STI) and clients using condoms in Thailand 1982–1997.
 Source: World Health Organization 2005 *Integrating STI/RTI Care for Reproductive Health: Sexually Transmitted and Other Reproductive Tract Infections: a Guide to Essential Practice*. WHO, Geneva.
 Adapted from: *Sentinel Serosurveillance*, Division of Epidemiology, Ministry of Health, Thailand.

STIs. Rapid succession of monogamous relationships or a number of sexual partners increases the risk considerably. Couples separated from each other for long intervals (e.g. due to travel or business, migrant workers, military) are also at increased risk of STIs, and preventative measures should be employed.

Safe sex and barrier contraception

Male and female condoms are widely regarded as the most reliable methods for protection and prevention from STIs if used correctly and consistently. The latex male condom may fail if handled or stored incorrectly, or used with lubricants that may damage the material. The female condom, made of polyurethane plastic, is equally protective against STIs, empowers women to have control of their protection and can be used with any lubricants.

Contact prevention

A high index of suspicion for PID, prompt recognition of STIs and effective treatment reduces the probability of disseminating infection in the community. However, this is not always possible, and contact tracing protocols should be in place to screen and treat sexual partners.

Screening

Detection of asymptomatic lower genital tract infections is crucial to preventing PID. Screening may be undertaken at any time when a speculum examination is done for another reason, during pregnancy or targeted for at-risk populations such as 15–24 year olds, sex workers and others who are at higher risk of STIs. Similarly, when a woman presents herself with vague symptoms of lower abdominal discomfort, intermenstrual bleeding or dyspareunia, tests should be undertaken to exclude the presence of genital infections, especially

chlamydia or gonorrhoea. Screening may also be undertaken prior to transcervical interventions.

Screening programmes and identifying populations at risk

A screening programme is a control and prevention project usually targeted at the highest risk group in order to maximize benefit and be cost-effective. In 2003, two pilot chlamydia screening programmes in England demonstrated that opportunistic screening using urine samples is practical and acceptable, and that the frequency of chlamydia infection in women using these services (including non-GU medicine services) was substantial (Pimenta et al 2003a,b). Subsequently, the Chlamydia Screening Studies (ClaSS) project (Low et al 2007), which screened 19,773 women and men aged 16–39 years selected from general practice lists, used urine and (for women) vulvovaginal swab specimens self-collected at home and sent to a laboratory for chlamydia testing. This study demonstrated that chlamydia infection in the general population was highest in those under 25 years of age, with similar results in men and women. Furthermore, self-collected urine specimens and vulvovaginal swabs were found to be suitable for diagnostic testing using NAATs (Low et al 2007).

Evidence for the effectiveness of chlamydia screening emanates from randomized controlled trials that have demonstrated reductions in the risk of PID among women screened for chlamydia. In the USA, Scholes et al (1996) reported that, at 12 months, women screened for chlamydia had a reduced risk of PID (8/10,000 woman-months) compared with the usual care arm (18/10,000 woman-months), resulting in a relative risk reduction of 56% among those screened. In Denmark, Ostergaard et al (2000) showed that, at 12 months, women offered home-sample screening for chlamydia had reduced prevalence of infection and diagnoses of

PID (2.9%) compared with women offered clinic services (6.6%), and 2.1% of the home group were treated for PID compared with 4.2% of the control group. Additionally, it has been reported that the incidence of PID and ectopic pregnancy has declined in a number of countries conducting chlamydia screening, including Sweden, the USA and Canada (Hillis et al 1995, Kamwendo et al 1996, Egger et al 1998, Sutton et al 2005, Rekart et al 2009). Turner et al (2006), using mathematical modelling, estimated that annual screening of 30% of men and women under 25 years of age with 20% partner notification would reduce the population prevalence of chlamydia by 29% after 1 year, 68% after 5 years and 82% after 10 years. If screening coverage was increased to 50%, the estimated reductions in prevalence would be 40% after 1 year, 79% after 5 years and 89% after 10 years, with an even greater decline in prevalence if partner notification rates were higher. Such mathematical modelling estimates are not without limitations, and several important parameters such as the prevalence of undiagnosed/untreated chlamydia, patterns of sexual contacts and chlamydia transmission, and the rate of progression to PID may affect the ultimate effectiveness of screening (US Preventive Services Task Force 2007). In a meta-analysis, Low et al (2009) reported that register-based chlamydia screening of high-risk women and female and male high school students reduced the incidence of PID in women at 1 year, and that opportunistic screening in women undergoing surgical termination of pregnancy reduced postabortion rates of PID compared with no screening. Low et al (2009) concluded that there was no evidence to support opportunistic screening in the general population under 25 years of age. Evidence suggests that a screening programme may be cost-effective at prevalences of 3.1–10% (Honey et al 2002), and that as there is high prevalence of asymptomatic infection in men, efforts to screen them for chlamydia should be strengthened.

In 2009, among the UK home nations, only England has a national chlamydia screening programme. In Wales, Scotland and Northern Ireland, advice varies and individuals can request confidential screening from their general practitioners or GU medicine clinics. High-risk 15–24 year olds are offered testing when they attend healthcare institutions.

In Europe, chlamydia is one of the most common STIs, with rates among young sexually active people ranging between 5% and 10%. The number of diagnosed cases is

increasing due to more cases being diagnosed and the use of more sensitive tests. The European Centre for Disease Control monitors chlamydia control activities in 29 European countries, including the 24 member states. In Canada, chlamydia is one of three nationally reportable STIs, and its infection rates have been increasing since 2007. There are national screening guidelines for sexually active and high-risk individuals. In the USA, chlamydia is the most frequently reported STI, and national chlamydia testing recommendations have been in place since 1993. In 2008, the CDC partnered with a number of non-profit organizations to form a 'US Chlamydia Coalition'. In Australia, chlamydia is the most commonly diagnosed STI, and the federal government has provided funding to increase chlamydia awareness, improve surveillance and undertake a pilot chlamydia testing programme as well as chlamydia prevention projects targeting high-risk groups.

Prevention of iatrogenic infections

PID due to iatrogenic infection is preventable by reducing the risks associated with vaginal or cervical interventions. Good antenatal care, safe delivery practices, good postabortion care and management of complications are accepted standards in developed countries, and have resulted in a dramatic decline in maternal morbidity; however, iatrogenic infection remains a major cause of PID in the developing world. Similarly, the risk of infection following transcervical procedures depends on the background STI prevalence, resource and capacity level, and conditions under which procedures are performed. Applying appropriate infection prevention measures, aseptic techniques and treating any existing cervical infection will reduce the risk of PID considerably.

Prevention of endogenous infections

Infections with bacterial vaginosis and *Candida albicans* are common and can be easily treated. However, their role in PID is debatable. Factors such as pregnancy, use of the oral contraceptive pill, chronic medical illnesses such as diabetes or HIV, and long-term use of steroids or antibiotics increase the risk of vaginal infections. Personal hygiene and elective treatment of high-risk patients will ensure the prevention of such infections.

KEY POINTS

1. Ascending chlamydial infection is the most common cause of PID.
2. Women under 25 years of age are the highest risk group.
3. Clinical presentation can range from no symptoms to very severe disease.
4. Delay in treatment increases the risk of long-term complications.
5. Treatment for suspected PID includes pain management, appropriate antibiotics, contact tracing, counselling and, occasionally, surgical intervention.
6. A screening programme is a control and prevention project, usually targeted at the highest risk group.
7. Prevention of PID is most effectively achieved through avoiding exposure to STIs/RTIs, and endogenous or iatrogenic infections.
8. Long-term sequelae include tubal factor infertility, ectopic pregnancy and chronic pelvic pain.
9. PID is a sexually transmitted infection with potentially harmful sequelae often managed suboptimally by physicians with little interest in the condition.
10. PID is the only preventable cause of infertility.
11. Screening for *Chlamydia trachomatis* is the most effective method of preventing PID.
12. The accuracy of syndrome diagnosis of PID should be improved by simple tests for the presence of lower genital tract infection.

Introduction

Sexually transmitted infections (STIs) are infections whose primary route of transmission is through sexual contact. They are common, often occult in nature, have serious sequelae and are synergistic with human immunodeficiency virus (HIV). In developing countries, they are the second most common cause of death amongst women aged 15–44 years, after maternal mortality. The serious nature of many of these conditions and the fact that the presence of one STI suggests the possibility of others is a caution to the gynaecologist to manage such patients with appropriate input from others, notably genitourinary physicians and microbiologists.

More than 20 pathogens are transmissible through sexual intercourse. Many are curable but, in spite of the availability of effective treatment, they remain a major public health concern in both industrialized and developing countries.

Globally, the exact prevalence of STIs is largely unknown. Surveillance systems exist in some countries but the data rendered are not always reliable or complete. The quality and completeness of the available data and estimates depend on the quality of STI services, the extent to which patients seek health care, the intensity of case finding and diagnosis, and the quality of reporting.

The completeness is further affected by the natural history of STIs, since a large number of infections are asymptomatic. Moreover, only part of the symptomatic population seeks health care and an even smaller number of cases are reported. The social stigma that is usually associated with STIs may result in people seeking care from alternative providers or not seeking care at all. As a result, report-based STI surveillance systems tend to underestimate the total number of new cases substantially.

World Health Organization (WHO) estimates suggest that more than 12 million new cases of syphilis, 62 million new cases of gonorrhoea, 92 million new cases of chlamydial infection and 174 million new cases of trichomoniasis occurred throughout the world in 1999 (World Health Organization 2001). Congenital syphilis, prevention of which is relatively easy and cost-effective, may still be responsible for as many as 14% of neonatal deaths. Up to 10% of women who are untreated, or inadequately treated, for chlamydial and gonococcal infections may become infertile as a consequence. On a global scale, up to 4000 newborn babies each year may become blind because of gonococcal and chlamydial ophthalmia neonatorum (note: ophthalmia neonatorum is a notifiable disease).

Both symptomatic and asymptomatic infections can lead to the development of serious complications with severe consequences. The most serious complications and

long-term consequences of untreated STIs tend to be in women and newborn babies. Sequelae in women include recurring herpes episodes, pelvic inflammatory disease (PID), ectopic pregnancy, spontaneous miscarriage, premature rupture of the membranes, puerperal sepsis, tubal factor infertility and cervical cancer consequent to human papilloma virus (HPV) infection. Neonates may be born premature or even stillborn. They may be born with infection or the consequences of congenital syphilis.

STIs also enhance the sexual transmission of HIV infection. The presence of an untreated STI can increase the risk of both acquisition and transmission of HIV by a factor of up to 10. Ulcerative STIs disrupt the integrity of the protective tegument and increase the presence of HIV-susceptible cells (e.g. CD4 lymphocytes). Non-ulcerative STIs similarly increase HIV-susceptible cells in the area. Moreover, improvement in the management of STIs can reduce the incidence of HIV-1 infection in the general population by approximately 40%. STI prevention and treatment are, therefore, important components in HIV prevention.

Guidelines covering the majority of STIs exist within the UK. They discuss aspects relating to screening, diagnostic criteria, management and prevention. Crucially, they also set standards for audit, providing a tool for improvement in all these aspects in all units across the UK. They will be quoted from heavily in this chapter in condensed form. The guidelines are not primarily directed *per se* at gynaecologists, but it is of vital importance that specialists in this area are aware of them.

Epidemiology

WHO estimated that 340 million new cases of STIs occurred worldwide in 1999. The largest number of new infections occurred in South and South-east Asia, followed by sub-Saharan Africa, Latin America and the Caribbean. However, the highest rate of new cases per 1000 population occurred in sub-Saharan Africa (World Health Organization 2001).

In developing countries, STIs and their complications are among the top five disease categories for which adults seek health care. In women of childbearing age, STIs (excluding HIV) are second only to pregnancy as causes of morbidity and mortality.

Globally, the highest rates of STIs are generally found in urban men and women aged 15–35 years. On average, women become infected at a younger age than men.

In the UK, peaks in STI diagnoses occurred in the mid-to-late 1940s (post World War II) and from the mid 1960s through to the early 1980s [from the age of sexual liberation to the advent of acquired immunodeficiency syndrome (AIDS)]. From 1998 to 2007, there was a substantial increase in diagnoses of most STIs (overall 6%). Cases of uncomplicated gonorrhoea increased by 42%, while chlamydia increased by 150%. Chlamydia has been the most commonly reported STI since 2001, overtaking genital warts (see Figure 63.1).

The rapid increase in reports of STIs is probably, in part, due to a general deterioration in sexual health amongst young people and men who have sex with men. However, the greater acceptability of using genitourinary medicine

(GUM) services and new campaigns to encourage testing have also made a contribution. In 2000, the UK survey of sexual attitudes and lifestyle over 10 years reported that 30% of 15-year-old girls were sexually active and half of all UK teenagers were sexually active before 17 years of age. Consistent condom usage decreased by 3% over the period of study. Male homosexual activity increased, as did the prevalence of unsafe sex in this group, especially in London. The number of heterosexual partners also increased, and more people were engaging in concurrent relationships.

Certain ethnic minority groups are disproportionately affected by some STIs. In 2005, the GRASP (Gonococcal Resistance to Antimicrobials Surveillance Programme) survey found that Black Caribbeans accounted for 18% of gonorrhoea diagnoses at the clinics studied.

The UK population is mobile and certain groups are at particular risk, including tourists, professional travellers, immigrants and members of the armed forces. In addition, poverty, urbanization, social migration and war often increase levels of prostitution.

The important features in maintaining an STI in a community have been factored into the following formula:

$$R_0 = \beta cd$$

where R_0 is the average number of new infections that result from one infection, β is transmissibility, c is the average rate of acquiring partners, and d is the duration of infection.

If $R_0 > 1$, the rate of spread in a community will rise; if $R_0 < 1$, the rate of spread will fall. This gives the principles behind effective STI control. β can be reduced by promoting condom use and vaccination, c can be reduced by encouraging behavioural change, and d can be reduced by encouraging diagnosis, treatment and contact tracing. These principles then translate into effective health education. d can also be reduced by screening.

Screening

There are guidelines for routine screening in pregnancy in the UK, and the current programme screens all pregnant women at booking for syphilis, hepatitis B and HIV after a pretest discussion. In addition, screening for hepatitis C should be undertaken in intravenous drug users. There is also a national screening programme for *Chlamydia trachomatis*.

In the UK, the National Institute for Health and Clinical Excellence (NICE) issued guidelines entitled 'Prevention of sexually transmitted infections and under 18 conceptions' in 2007. These guidelines were not specifically aimed at gynaecologists but more at primary care agencies. In summary, these guidelines set recommendations as follows.

Recommendations 1 and 2: for key groups at risk of STIs

- Identify individuals at high risk of STIs using their sexual history. Opportunities for risk assessment may arise during consultations on contraception, pregnancy or abortion, and when carrying out a cervical smear test, offering an STI test or providing travel immunization. Risk assessment can also be

Figure 63.1 All new episodes of sexually transmitted infections seen in genitourinary medicine clinics 1998–2007.

Source: Health Protection Agency 2008 All new episodes seen at GUM clinics: 1998–2007. United Kingdom and country specific tables.

carried out during routine care or when a new patient registers.

- Have one-to-one structured discussions with individuals at high risk of STIs (if trained in sexual health), or arrange for these discussions to take place with a trained practitioner. The discussions should be structured on the basis of behaviour change theories. They should address factors that

Box 63.1 Essential questions in a history enquiring about sexual infection

- When did she last have sexual intercourse?
- What is the nature of her sexual activity? (hetero-/homo-/bisexual) (oral/anal/vaginal)
- When did she last have sexual intercourse with anyone else other than that person?
- Was a barrier method of contraception used?
- Was any method of contraception used? (risk of pregnancy)
- Travel history (and that of the partner)
- History of intravenous drug abuse
- History of giving or accepting money for sex
- History of previous STIs

can help to reduce risk-taking and improve self-efficacy and motivation. Ideally, each session should last for at least 15–20 min. The number of sessions will depend on individual need.

Recommendation 3: patients with an STI

- Help patients with an STI to get their partners tested and treated (partner notification), when necessary. This support should be tailored to meet the patient's individual needs. If necessary, refer patients to a specialist with responsibility for partner notification. Partner notification may be undertaken by the health professional or by the patient.
- Provide the patient and their partners with infection-specific information, including advice about possible reinfection. For chlamydia infection, also consider providing a home sampling kit.

Information given to patients for any condition should be supported by written evidence-based information, in a clear, jargon-free format, to reinforce the message.

Principles of Management of Sexually Transmitted Infections

History

Whilst in the UK, STIs are principally managed by specialist clinics (GUM), STIs also commonly present to the gynaecologist. The threshold at which the gynaecologist should take a sexual history is correspondingly low. The essentials are establishment of a rapport, privacy and confidence in the manner of questioning. Embarrassment on the part of the patient is quite understandable and should be dealt with empathetically. Phrases can be couched in terms such as 'I am sorry to have to ask you this, please don't be offended, it is important'. Essential elements of the sexual history, taken in combination with a general gynaecological and medical history, are shown in Box 63.1.

One of the markers for women at risk of STIs is the age range (15–34 years). This takes the age range down to childhood, and these patients frequently present with a parent. It is highly unlikely that a girl will reveal all matters regarding

her sexual activity in front of her mother. Such questions relating to this may be more profitably asked in the examination room with the mother back in the waiting room. In such cases, confidentiality should be emphasized and reassurance given that the information will not get back to her parents.

Examination

It is essential that a chaperone is present (irrespective of the gender of the examining doctor) and that consent has been obtained for intimate examination. Ideally, examination should be performed in lithotomy; in any case, there should be adequate exposure to allow thorough examination in good light of the external genitalia, mons pubis, perineum and perianal area. One should observe for *Pediculosis pubis* (crabs), scabies, *molluscum contagiosum*, warts, ulceration, excoriation, scars and any discharge from the introitus; and palpate for inguinal lymphadenopathy and tenderness. A bivalve speculum should be passed, gently, as the patient may find this uncomfortable. The cervix should be examined, looking for ectropion, warts, cervicitis and mucopurulent discharge. The vaginal walls should be observed for inflammation or warts. At this time, 'triple swabs' should be taken.

The first swab is taken from the posterior fornix and is placed into Stuart's transport medium (agar and charcoal). This swab essentially screens for *Trichomonas vaginalis*, bacterial vaginosis and *Candida* spp. The second swab is taken from the endocervix and is a screen for *Neisseria gonorrhoeae*; this is also placed into Stuart's transport medium. The third swab is also taken from the endocervix and is a screen for *C. trachomatis*. This last swab needs to be taken in a particular way as *C. trachomatis* is an obligate intracellular organism. Thus, to be sampled, the swab needs to pick up some cells from the sampled area. The swab should be rotated in the endocervix for at least a count of 10 and placed into chlamydia transport medium.

The speculum should then be removed and a digital examination performed. The patient should be examined for cervical excitation, uterine and adnexal tenderness, and adnexal masses.

Specialist clinic tests

In a GUM clinic, further refinements to this examination include a test of vaginal pH using narrow-range pH paper. The normal vaginal pH is 3.8–4.5. Bacterial vaginosis, trichomoniasis and atrophic vaginitis often cause a vaginal pH higher than 4.5. For a 'whiff test', several drops of a potassium hydroxide solution are added to a sample of the vaginal discharge. A strong fishy odour (ammonia) from the mix means that bacterial vaginosis is present. For a wet mount, a sample of the vaginal discharge is placed on a glass slide and mixed with a salt solution. The slide is looked at under a microscope (under dark ground illumination) for yeast cells, trichomoniasis and treponemes. A Gram stain is made of any discharge and examined for *N. gonorrhoeae* (Gram-negative diplococci) and the clue cells of bacterial vaginosis. Further swabs are frequently taken from the urethra, anus and throat, and sent in Stuart's transport medium for culture (looking for *N. gonorrhoeae*). Any woman

reporting anal intercourse will also undergo proctoscopy looking for warts.

If one STI is present, there may be others. In practice, a patient with an STI will be referred to a GUM clinic, counselled and offered a full screen including serological tests for syphilis, hepatitis B, HIV and hepatitis C, if indicated. The GUM clinic will also arrange for contact tracing to break the chain of infection. They may also arrange for a follow-up test of cure.

If drug treatment is given, it is better to use simple, if possible, single-dose regimes and advise the woman to abstain from intercourse during treatment to prevent reinfection until her partner is also treated. In practice, regimens are given that will cover *N. gonorrhoeae*, *C. trachomatis*, *T. vaginalis* and bacterial vaginosis.

In the spirit of the NICE guidelines, time should be allocated to discuss modification of any high-risk activity to prevent reinfection (National Institute for Health and Clinical Excellence 2007). This should be non-judgmental and should be accompanied by written information on the subject to reinforce the message.

Clinical Presentations

Patients present with clinical syndromes rather than microbiological presentations. In fact, the most common presentation is none whatsoever! The patient is picked up on opportunistic screening, by partner notification or by chance when presenting with another condition. This emphasizes the importance of the NICE guidelines, especially in the light of increasing prevalences of STIs in the UK.

Vaginal infection and/or cervicitis may present with a discharge, and cervicitis may also present as postcoital bleeding. Endometritis may cause erratic bleeding and pelvic pain. Adnexitis is synonymous with acute PID and may produce dyspareunia and pelvic pain. Fitz-Hugh-Curtis syndrome consists of right upper quadrant pain resulting from ascending pelvic infection and inflammation of the liver capsule or diaphragm.

Genital Herpes

Genital ulcers have a broad differential diagnosis, but the most common cause of de-novo and recurring multiple painful ulceration is herpes simplex virus (HSV). The infection is lifelong and has the potential for recurrence. It can be managed but not eradicated. It is a disease that has long been in the public domain with varying levels of informed and misinformed knowledge. A patient with this diagnosis needs careful counselling, explanation and support. Between 1998 and 2007, diagnoses of genital herpes rose by 51% in the UK.

Aetiology

Herpes simplex virus 1 and 2 (HSV-1 and HSV-2) are species of *Herpesviridae*, which cause genital herpes. Herpes viruses are composed of relatively large double-stranded, linear DNA genomes encoding 100–200 genes encased within an icosahedral proteinaceous capsid which is wrapped in a lipid bilayer envelope. They are nuclear, replicating the viral DNA

being transcribed to RNA within the infected cell's nucleus. HSV enters a latent phase within the neurones (local sensory ganglia) between active symptomatic episodes. Reactivation leads to production of virions, which may then be passed to a new host by sexual contact (in the case of genital herpes). Genital HSV-2 recurs and sheds more often than genital HSV-1; the converse is true for oral herpes.

Clinical features

Only about half those infected will get symptoms at the time of infection. Some may become symptomatic at a later date and some not at all. The seropositivity rates are 7% in the UK, 22% in the USA and 40% in 19-year-old females in Tanzania. In those cases that become symptomatic, the incubation period is 7–14 days.

The first episode presents with multiple painful genital ulcers (see Figure 63.2). It is less severe in those with a history of oral herpes. Typical lesions begin as vesicles, at any or all sites from the introitus to the cervix, which become superficial tender ulcers with an erythematous halo and a yellow or grey base (Figure 63.3). Immunocompromised patients may have an atypical appearance which is an elongated 'knife cut' ulcer. There may be bilateral inguinal lymphadenopathy. Viral shedding continues until the lesions crust over. One-third of patients have systemic symptoms of fever and general malaise. Ten percent will experience viral meningitis with photophobia and headache. A few patients experience retention of urine, either because of pain due to passing urine over the lesions (in which case, micturating in a bath may help) or because of a viral autonomic neuritis. Involvement of other nerves may lead to hyperaesthetic buttocks, thighs or perineum for a time. Severe encephalitis is rare but may be seen more frequently in immunocompromised patients. Without treatment, the first episode lasts for 3–4 weeks.

Figure 63.2 Primary genital herpes: multiple painful ulcers are present.
From Bologna J et al, *Dermatology* 2e, with permission of Elsevier.

Complications of the first episode are common. There may be secondary bacterial infection of lesions. Autoinoculation may occur, often to fingers and eyes.

Recurrent episodes occur in approximately half of patients, tend to be less severe and are relatively less common after the first year. HSV-2 is more likely to become recurrent than HSV-1. There does not necessarily have to be a precipitating event, although stress, menstruation, trauma (sexual intercourse) and ultraviolet light are implicated. Immunosuppression increases the frequency and duration of episodes; herpetic ulceration persisting for over 1 month in a patient with HIV is AIDS defining.

Diagnosis

In the UK, guidelines for diagnostic criteria for herpes were drawn up by the British Association for Sexual Health and HIV (BASHH) in 2006. These are summarized below.

Screening of asymptomatic GUM clinic attendees by either HSV antibody testing or HSV detection in genital specimens is not recommended at present, although this area is under active review.

Virus detection and characterization

The confirmation and characterization of the infection and its type, by direct detection of HSV in genital lesions, are essential for diagnosis, prognosis, counselling and management. Methods should be used that directly demonstrate HSV in swabs taken from the base of the genital lesion. Virus typing to differentiate between HSV-1 and HSV-2 should be performed in all patients with newly diagnosed genital herpes. HSV isolation in cell culture is the current routine diagnostic method in the UK. Virus culture is slow, labour-intensive and expensive. Specificity is virtually 100%, but

Figure 63.3 Primary genital herpes: ulcers on cervix.

levels of virus shedding, quality of specimens, and sample storage and transport conditions influence sensitivity. Delayed sample processing and lack of specimen refrigeration after collection and during transport significantly reduce the yield of virus culture at all stages of infection.

HSV DNA detection by polymerase chain reaction (PCR) increases HSV detection rates by 11–71% compared with virus culture. PCR-based methods allow less stringent conditions for sample storage and transport than virus culture, and new real-time PCR assays are rapid and highly specific. Real-time PCR is recommended as the preferred diagnostic method for genital herpes.

Serology

Testing for HSV type-specific antibodies can be used to diagnose HSV infection by the detection of HSV-1 IgG or HSV-2 IgG or both. It is difficult to say whether the infection is recent, as immunoglobulin M (IgM) detection is unreliable. Collection of serum samples a few weeks apart can be used to show seroconversion. HSV-2 antibodies are indicative of genital herpes, whereas HSV-1 antibodies do not differentiate between genital and oropharyngeal infection.

Western blot is the diagnostic gold-standard, but it is not commercially available. Several commercial assays, as well as validated in-house methods, are available which show 91–99% sensitivity and 92–98% specificity relative to Western blot in sexually active adults.

Caution is needed in interpreting serology results because even highly sensitive and specific assays have poor predictive values in low-prevalence populations. Local epidemiological data and patient demographic characteristics should guide testing and interpretation of results. In patients with a low likelihood of genital herpes, a positive HSV-2 antibody result should be confirmed in a repeat sample or by a different assay.

The differential diagnosis of vulval ulcers is shown in Table 63.1.

Treatment

First episode of genital herpes

Saline bathing should be advised and oral analgesia provided. Topical anaesthetic agents, such as 5% lidocaine (lignocaine) ointment, may be useful to apply, especially

prior to micturition, but should be used with caution because of the risk of potential sensitization.

Oral antiviral drugs are indicated within 5 days of the start of the episode and while new lesions are still forming.

Aciclovir, valaciclovir and famciclovir all reduce the severity and duration of episodes. Antiviral therapy does not alter the natural history of the disease. Topical agents are less effective than oral agents. Combined oral and topical treatment is of no benefit. Intravenous therapy is only indicated when the patient cannot swallow or tolerate oral medication because of vomiting. There is no evidence for benefit from courses longer than 5 days. However, it may be prudent to review the patient after 5 days and continue therapy if new lesions are still appearing at this time.

Recommended regimens (all for 5 days)

- Aciclovir 200 mg five times daily.
- Aciclovir 400 mg three times daily.
- Valaciclovir 500 mg twice daily.
- Famciclovir 250 mg three times daily.

Hospitalization may be required for urinary retention, meningism and severe constitutional symptoms. If catheterization is required, suprapubic catheterization is preferred to prevent the theoretical risk of ascending infection, to reduce the pain associated with the procedure, and to allow normal micturition to be restored without multiple removals and recatheterizations.

Recurrent genital herpes

Recurrences are self-limiting and generally cause minor symptoms. Management decisions should be made in partnership with the patient. Strategies include supportive therapy alone, episodic antiviral treatments and suppressive antiviral therapy. The best strategy for managing an individual patient may change over time according to recurrence frequency, symptom severity and relationship status.

General advice includes saline bathing, Vaseline, analgesia and 5% lidocaine (lignocaine) ointment.

Episodic antiviral treatment (oral aciclovir, valaciclovir and famciclovir) reduces the duration (by median of 1–2 days) and severity of recurrent genital herpes. Patient-initiated treatment started early in an episode is most likely to be effective.

Recommended regimens (all for 5 days)

- Aciclovir 200 mg five times daily.
- Aciclovir 400 mg three times daily.
- Valaciclovir 500 mg twice daily.
- Famciclovir 125 mg twice daily.

Short-course therapies

- Aciclovir 800 mg three times daily for 2 days.
- Famciclovir 1 g twice daily for 1 day.
- Valaciclovir 500 mg twice daily for 3 days.

Suppressive antiviral therapy

Patients who have taken part in trials of suppressive therapy have had at least six recurrences per annum. Such patients have fewer or no episodes on suppressive therapy. Patients

Table 63.1 The differential diagnosis of genital ulcers

Infective	Non-infective
Herpes simplex virus	Aphthous ulcers
Primary syphilis	Trauma
Lymphogranuloma venereum	Skin disease (e.g. lichen sclerosis et atrophicus) Chancroid
Donovanosis	Behçet's syndrome
Human immunodeficiency virus	Other multisystem disorder (e.g. sarcoidosis)
	Dermatitis artefacta

with lower rates of recurrence will probably also have fewer recurrences with treatment.

Patient safety and resistance data for long-term suppressive therapy with aciclovir now extends to over 18 years of continuous surveillance.

Recommended regimens

- Aciclovir 400 mg twice daily.
- Aciclovir 200 mg four times daily.
- Famciclovir 250 mg twice daily.
- Valaciclovir 500 mg once daily.

If breakthrough recurrences occur on standard treatment, the daily dosage should be increased (e.g. aciclovir 400 mg three times daily). Suppressive therapy should be discontinued after a maximum of 1 year to reassess recurrence frequency. The minimum period of assessment should include two recurrences. Patients who continue to have unacceptably high rates of recurrence may restart treatment.

Condoms may be partially effective in preventing acquisition of HSV, especially in preventing transmission from infected males to their female sexual partners. The efficacy of male condoms in preventing transmission from infected females to uninfected male partners has not been demonstrated, and the efficacy of female condoms to reduce HSV transmission during intercourse has not been assessed.

Suppressive antiviral therapy with valaciclovir 500 mg once daily reduces the rate of acquisition of HSV-2 infection and clinically symptomatic genital herpes in serodiscordant couples. In a randomized trial involving 1484 patients treated for 8 months, 0.5% valaciclovir recipients developed symptomatic infection compared with 2.2% of placebo recipients (75% reduction); however, 60 people needed to be treated to prevent one transmission. Other antivirals may be effective but efficacy has not been proven in clinical trials.

Diagnosis often causes considerable distress. Counselling should be as practical as possible and should address particular personal situations. The Family Planning Association (FPA) produces a range of leaflets on sexual health for the UK National Health Service (NHS). Their leaflet on genital herpes provides comprehensive patient information based on the BASHH guidelines, and can be purchased or viewed as a non-printable PDF file on the FPA website.

No vaccines have been approved for prevention of genital herpes, although trials are ongoing. Published studies using the HSV-2 glycoprotein-D adjuvant vaccine have shown limited efficacy in preventing clinical disease, and only in women who were seronegative for both HSV-1 and HSV-2 at baseline. The guideline authors do not support the use of unauthorized or unlicensed vaccines outside of clinical trials.

Management of herpes in pregnancy and neonatal herpes prevention

Guidelines for genital herpes in pregnancy are categorized into management of first episodes and recurrent episodes. Accurate clinical classification is difficult. Viral isolation and typing and the testing of paired sera (if a booking specimen is available) may be helpful. Referral to a genitourinary physician for advice on management of women with suspected genital herpes is recommended.

First-episode genital herpes

First-episode genital herpes has been associated with first-trimester miscarriage; however, there is no conclusive evidence that it causes developmental abnormality if the pregnancy continues. The occurrence of first-episode genital herpes is not considered an indication for termination of pregnancy (TOP). An anomaly scan may be considered at 20–22 weeks of gestation where this is not routine. Management should be in line with the clinical condition, with the use of either oral or intravenous aciclovir. Although aciclovir is not licensed for use in pregnancy, there is substantial clinical experience supporting its safety. Vaginal delivery should be anticipated.

Daily suppressive aciclovir from 36 weeks of gestation may be considered for women who experience first-episode genital herpes in order to reduce the likelihood of HSV lesions at term, and negate an offer of caesarean section (CS) delivery. There are sound arguments for using aciclovir 400 mg three times daily because of the altered pharmacokinetics of the drug in late pregnancy.

Third-trimester acquisition

CS for the prevention of neonatal herpes has not been evaluated in randomized controlled trials. CS should be offered to all women presenting with first-episode genital herpes lesions at the time of delivery, or within 6 weeks of the expected date of delivery or onset of labour. However, CS may not be of benefit in reducing transmission for women presenting with ruptured membranes for greater than 4 h. In all these cases, the paediatricians should be informed. Continuous aciclovir in the last 4 weeks of pregnancy reduces the risk of both clinical recurrence at term and delivery by CS.

Recurrent genital herpes

Antiviral treatment is rarely indicated for treatment of recurrent episodes of genital herpes during pregnancy. Symptomatic recurrences during the third trimester are likely to be brief, and vaginal delivery is appropriate if no lesions are present at delivery.

CS should be considered for women with recurrent genital herpes lesions at the onset of labour. Recurrent genital herpes at any other time during pregnancy is not an indication for delivery by CS. The risks of vaginal delivery for the fetus are small and must be set against risks to the mother of CS.

Syphilis

There was a post World War II peak in the incidence of syphilis, but with the advent of penicillin, it became one of the less common STIs in the UK. However, infectious syphilis is reported to have increased by a factor of 19 between 1998 and 2007 (2680 new diagnoses in that year). To a large extent, this rise has been fuelled by syphilis outbreaks among male homosexuals.

Nevertheless, the most dramatic recent increases in syphilis cases have been among women and heterosexual men. Although the numbers involved are considerably lower than those for chlamydia, this is still a worrying trend as syphilis can have serious health implications (left untreated, syphilis

can damage the heart, aorta, brain, eyes and bones, and can be fatal) and had been thought for years to be under control in the UK.

Globally, WHO estimates that there are 12 million new cases of syphilis each year, most of which occur in South and South-east Asia, and sub-Saharan Africa. Infectious syphilis is reaching epidemic proportions in states of the former Soviet Union, and is increasingly substantially in the USA, especially in the African-American population.

Aetiology

Treponema pallidum venereum or *Treponema pallidum pallidum* is a motile spirochaete, entering the host via breaches in epithelium. The organism can also be transmitted vertically to a fetus in the later stages of pregnancy, giving rise to congenital syphilis.

The subspecies of *T. pallidum* causing yaws (*pertenue*), pinta (*carateum*) and bejel or endemic syphilis (*endemicum*) are morphologically and serologically indistinguishable from *T. pallidum pallidum* (syphilis); however, their transmission is not venereal in nature and the course of each disease is significantly different. They are worthy of mention as they can cause diagnostic confusion. Yaws occurs in sub-Saharan Africa, the Caribbean and most of the humid tropics. Bejel occurs in desert regions, and pinta occurs in parts of Central and South America. If venereal syphilis cannot be excluded in someone originating from one of these areas, it is safest to treat.

Clinical features

Primary syphilis

The incubation period after inoculation is 9–90 days (mean 21 days). The lesions may be extragenital and may be multiple. Chancres are usually painless, raised, well-circumscribed ulcers (Figure 63.4). There is a non-tender regional lymphadenopathy. The lesion may well go unnoticed, especially if it is intravaginal or rectal. It will heal spontaneously in 3–10 weeks.

Secondary syphilis

The lesions of secondary syphilis usually manifest some 4–8 weeks after the appearance of the chancre, but sometimes up to 6 months later. In one-third of cases, the chancre is still there. There is a systemic eruption of a non-itchy maculopapular rash, symmetrical and involving the palms and soles (Figure 63.5). Papular lesions may coalesce into large fleshy wart-like lesions, condylomata lata, in areas such as the anus and the labia. Mucous patches and linear (snail-track) ulcers are seen on the mucosae. There may be a generalized lymphadenopathy. The secondary stage involves a bacteraemia with fever, headache, bone pain, alopecia, arthritis and meningitis. There may be hepatitis, optic neuritis and papilloedema. A sensorineural deafness can occur due to destruction of hair cells in the inner ear.

Without treatment, the lesions of secondary syphilis resolve. Approximately one-quarter of cases will have a recurrence of secondary syphilis; although unusual after 1 year, it can recur up to 2 years later, during which time the infection can be transmitted to a sexual partner.

Figure 63.4 The chancre of primary syphilis.

From Morse S et al., *Atlas of Sexually Transmitted Diseases and AIDS*, 3e, with permission of Elsevier.

Figure 63.5 Secondary syphilis: the maculopapular rash.

Syphilis is transmissible to other adults through sexual contact in primary and secondary syphilis and, occasionally, in early latent syphilis.

Latent syphilis

- Early: the disease has been present for less than 2 years; this is the time when relapse into secondary syphilis may occur.
- Late: the disease has been present for more than 2 years.

Late sequelae

Approximately one-third of cases will go on to develop late clinical sequelae. Of all cases infected with syphilis who are untreated, 10% of men and 5% of women will develop neurosyphilis, sometimes within 5 years. Meningovascular syphilis presents most commonly with headache, and sometimes with signs akin to a stroke with palsies of cranial nerves III, VI, VII and VIII. Rarely, there may be hemiplegia. Argyll Robertson pupils are a manifestation; they accommodate but do not react to light. Parenchymatous neurosyphilis presents as general paresis of the insane or, as a consequence of degeneration of the posterior columns, tabes dorsalis. The latter presents with ataxia, failing vision, sphincter disturbances and attacks of severe pain. Approximately 20% of cases will develop cardiovascular syphilis; many years later, this may manifest as a thoracic aortic aneurysm or aortic regurgitation. Gummas develop 3–12 years later in 15% of cases. They may occur on the skin, mucous membranes and, more rarely, bone or viscera.

Diagnosis

Dark ground microscopy of a wet preparation scraped from the base of a chancre or a lesion of secondary syphilis will display the treponeme as a bluish-white thread-like organism with a coiled body, some 6–20 µm long (Figure 63.6). It is motile and displays three distinct movements: watch-spring, corkscrew and jack-knife. Due to sensitivity and specificity issues with serological testing, this is by far the best chance of establishing a firm diagnosis.

Dark ground/dark field microscopy (DGM) of lesion exudate or lymph nodes should be performed by experienced clinicians because of interference from commensal spirochaetes that are found in the normal flora of the genital and rectal mucosae. DGM is considered to be less reliable in examining rectal and non-penile genital lesions, and is not suitable for examining oral lesions.

If the initial examination is negative, DGM should be repeated daily for at least 3 days. Antibiotics should be withheld during this period, and local saline lavage may be used to reduce local sepsis.

Testing of material submitted on dry swabs by PCR is recommended for oral or other lesions where contamination with commensal treponemes is likely.

PCR is also useful in the diagnosis of primary syphilis and is available via local laboratories sending samples to the Sexually Transmitted Bacteria Reference Laboratory at the Health Protection Agency.

Serological tests can be divided into non-specific tests [Venereal Disease Reference Laboratory (VDRL) and rapid plasmin reagin (RPR)] and specific tests [*T. pallidum* enzyme immunoassay (EIA), fluorescent treponemal antibody (FTA), *T. pallidum* haemagglutination assay (TPHA) and *T. pallidum* particle assay]. Non-specific tests usually become negative after successful treatment, whereas specific tests remain positive. All tests, specific or otherwise, are positive for bejel, yaws and pinta.

Non-specific tests become positive 3–5 weeks post inoculation, and as they are quantitative, they may be used to monitor treatment. However, they may also decay naturally, even yielding false-negative results. They may also

Table 63.2 Diagnosis and serological interpretation

Results positive	Diagnosis
None	Syphilis not present or very early primary syphilis
All	Untreated, recently treated or latent syphilis
<i>T. pallidum</i> EIA (or FTA) and VDRL	Primary syphilis
<i>T. pallidum</i> EIA (or FTA) and TPHA	Treated syphilis or untreated late latent or late syphilis
<i>T. pallidum</i> EIA or FTA only	Early primary syphilis, untreated or recently treated early syphilis
VDRL/RPR only	False positive reaction
EIA, enzyme immunoassay; FTA, fluorescent treponemal antibody; VDRL, Venereal Disease Reference Laboratory; TPHA, <i>Treponema pallidum</i> haemagglutination assay; RPR, rapid plasmin reagin.	

give false-positive results in the presence of active herpes, measles, mumps, chronic autoimmune disease and rheumatoid arthritis, and also after immunization for typhoid or yellow fever.

EIA tests become positive soon after infection (3–4 weeks, similar to the FTA) and have the advantage of being easy to automate.

A guide to interpretation of tests is given in Table 63.2.

The UK Department of Health has reviewed the current practice of offering syphilis testing routinely for pregnant women, and has recommended that screening for syphilis should continue. EIA is gradually replacing VDRL/RPR and TPHA as a screening tool by recommendation of the UK Public Health Laboratory Service.

Management

Box 63.2 shows the guidelines of therapeutic regimens approved by BASHH in 2008 for the treatment of syphilis.

With parenteral therapy with penicillin, the Jarisch–Herxheimer reaction is common in both primary and secondary

Box 63.2 Guidelines of therapeutic regimens approved by BASHH in 2008 for the treatment of syphilis

Incubating syphilis/epidemiological treatment

- Benzathine penicillin G 2.4 MU intramuscularly, single dose.
- Doxycycline 100 mg orally twice daily for 14 days.
- Azithromycin 1 g orally stat.

Early syphilis (primary, secondary and early latent)

- Benzathine penicillin G 2.4 MU intramuscularly, single dose.
- Procaine penicillin G 600,000 units intramuscularly once daily for 10 days.

Alternative regimens may be required for those with penicillin allergy or refusing parenteral treatment

- Doxycycline 100 mg orally twice daily for 14 days.
- Azithromycin 2 g orally stat or 500 mg once daily for 10 days.
- Erythromycin 500 mg orally four times daily for 14 days.
- Ceftriaxone 500 mg intramuscularly once daily for 10 days (if no anaphylaxis to penicillin).
- Amoxycillin 500 mg orally four times daily plus probenecid 500 mg four times daily for 14 days.

Early syphilis in pregnancy

- Benzathine penicillin G 2.4 MU intramuscularly single dose in the first and second trimesters. When maternal treatment is initiated in the third trimester, a second dose of benzathine penicillin G 2.4 MU intramuscularly should be given after 1 week.
- Procaine penicillin G 600,000 unit intramuscularly once daily for 10 days.

Alternative regimens

- Amoxycillin 500 mg orally four times daily plus probenecid 500 mg orally four times daily for 14 days.
- Ceftriaxone 500 mg intramuscularly daily for 10 days.
- Erythromycin 500 mg orally four times daily for 14 days or azithromycin 500 mg orally once daily for 10 days plus evaluation and treatment of neonates at birth with penicillin.

Late/latent syphilis in pregnancy

- Benzathine penicillin 2.4 MU intramuscularly weekly for 2 weeks (three doses).
- Procaine penicillin 600,000 units intramuscularly once daily for 17 days.

Alternative regimens

- Amoxycillin 2 g orally three times daily plus probenecid 500 mg four times daily for 28 days.

syphilis. Patients should be warned about the possibility of flu-like illness after the first injection. The chancre may become larger initially or the rash may become more widespread. Reassurance and therapy with paracetamol and non-steroidal anti-inflammatory drugs are usually all that is necessary.

Congenital syphilis is preventable. Antenatal testing has always been cost-effective, and this is even more so with the increase in the prevalence of syphilis in the UK. *T. pallidum* can infect the fetus transplacentally at any time. This is less likely in late or latent syphilis (5%), but is very common in the first two stages (50%). In sub-Saharan Africa, it is associated with 25% of all stillbirths.

Lymphogranuloma Venereum

Aetiology

Lymphogranuloma venereum (LGV) is a systemic disease caused by one of three invasive serovars (L1, L2 or L3) of *C. trachomatis*, but other strains may occasionally be involved.

LGV has been a rare occurrence in industrialized countries since the mid-1960s. Since 2003, however, a series of LGV outbreaks have been reported in several European cities, starting in the Netherlands. In the UK, more than 290 cases had been confirmed by December 2005. The majority of cases have been diagnosed in GUM clinics in London. At that time, all new cases were among male homosexuals, the majority of whom were HIV positive.

LGV is endemic in several tropical areas, including East, West and Southern Africa; Madagascar; India; South-east Asia; Papua New Guinea; and some Caribbean islands. A large epidemic has been reported recently among crack cocaine users in the Bahamas.

Clinical features

The clinical course of LGV is classically divided into three stages.

Primary lesion

The incubation period is extremely variable (range 3–30 days) from the time of sexual contact with an infected individual. The primary lesion is transient and often imperceptible, in the form of a painless papule or pustule, or a shallow erosion. It is found on the coronal sulcus of males, and on the posterior vaginal wall, fourchette, vulva or, occasionally, cervix of females. Extragenital lesions have been reported, such as in the oral cavity (tonsil) and extragenital lymph nodes.

Secondary lesion, lymphadenitis, or lymphadenopathy or bubo

The most common clinical manifestation of LGV is tender inguinal and/or femoral lymphadenopathy that is typically unilateral (two-thirds of cases). It may involve one lymph node or the entire chain, which can become matted with considerable periadenitis and bubo formation, and may ulcerate and discharge pus from multiple points, creating chronic fistulae. When both inguinal and femoral lymph nodes are involved, they may be separated by the 'groove sign', separation of these two lymph node systems by the inguinal ligament. Lymphadenopathy commonly follows the primary lesion by a period of a few days to weeks (10–30 days, rarely months). The systemic spread of *C. trachomatis* may be associated with fever, arthritis, pneumonitis and, more rarely, perihepatitis.

Tertiary stage or the genito-ano-rectal syndrome

The vast majority of patients recover after the secondary stage without sequelae. A few patients develop proctitis, acute proctocolitis mimicking Crohn's disease, fistulae, strictures and a chronic granulomatous disfiguring condition of the vulva.

Long-term complications

The destruction of lymph nodes may result in lymphoedema of genitals (elephantiasis) with persistent suppuration and pyoderma.

Diagnosis

Positive diagnosis of LGV is difficult, requiring a combination of good clinical acumen and supportive investigations. LGV can be suspected on positive chlamydial serology, isolation of *C. trachomatis* from the infected site or histological identification of chlamydia in infected tissue. Traditional methods for LGV diagnosis have been reviewed based on nucleic acid amplification tests (NAATs).

Chlamydiae are intracellular organisms, so samples must contain cellular material which can be obtained from the ulcer base exudate or from rectal tissue, or by aspiration from fluctuant lymph nodes or buboes. A urethral swab or first-catch urine (FCU) sample can be used when lymphadenopathy is present and LGV is suspected as the cause.

Treatment

- First choice: doxycycline 100 mg twice daily orally for 21 days (or tetracycline 2 g daily or minocycline 300 mg loading dose followed by 200 mg twice daily).
- Second choice: erythromycin 500 mg four times daily orally for 21 days.

Chancroid

Aetiology

An infection caused by *Haemophilus ducreyi*, the global distribution is similar to that of LGV. Co-infections of *H. ducreyi* with *T. pallidum* or HSV are frequent and occur in over 10% of patients in many African studies. Chancroid is characterized by painful anogenital ulceration (multiple) and lymphadenitis with progression to bubo formation. The incubation period ranges between 3 and 10 days, and the initial lesion may progress rapidly to form an open sore. There are no prodromal symptoms.

In males, most ulcers are found on the prepuce near the frenulum or in the coronal sulcus. In females, most lesions are found at the entrance of the vagina, particularly the fourchette. Several lesions may merge to form gigantic ulcers.

Diagnosis

The main methods revolve around the identification of *H. ducreyi* by: culture of material obtained from the ulcer base on specialized agar; detection of nucleic acid (DNA) by amplification techniques such as PCR; using nested techniques; microscopy of a Gram-stained smear (or other stains) of material from the ulcer base or of pus aspirate from the bubo; or demonstration of characteristic Gram-negative coccobacilli, with occasional characteristic chaining. The test has low sensitivity and is not recommended as a diagnostic test.

Treatment

- Azithromycin 1 g orally in a single dose.
- Ceftriaxone 250 mg intramuscularly in a single dose.
- Ciprofloxacin 500 mg orally in a single dose.
- Ciprofloxacin 500 mg orally twice daily for 3 days.
- Erythromycin 500 mg orally four times daily for 7 days.

Granuloma Inguinale (Donovanosis)

The following is a condensation of the 2001 guidelines for the management of donovanosis (granuloma inguinale) from the Clinical Effectiveness Group (Association for Genitourinary Medicine and the Medical Society for the Study of Venereal Diseases). This can be found on the BASHH website (<http://www.bashh.org>).

Aetiology

Donovanosis is seen chiefly in small endemic foci in tropical countries. In recent years, active foci of disease have been described in India, Papua New Guinea, the Caribbean, Brazil, the Guyanas, South Africa, Zambia, Vietnam and in Australian aboriginals. The causative organism, formerly *Calymmatobacterium granulomatis*, has recently been officially redesignated *Klebsiella granulomatis*.

Clinical features

At the site of primary inoculation, one or more papules/nodules develop into friable ulcers or hypertrophic lesions which gradually increase in size. Lesions do not tend to be painful. Regional lymphadenopathy is followed by either abscess formation (pseudobubo) or ulceration of the overlying skin. Untreated infections may either resolve spontaneously or persist and slowly spread. Primary lesions of mouth and cervix occur, and the latter have often been mistaken for malignant lesions. Complications include haemorrhage, genital lymphoedema, genital mutilation and cicatrization, development of squamous carcinoma and, on rare occasions, haematogenous dissemination to bone and viscera (particularly during pregnancy). Rare cases of vertical transmission have been reported. Lesions of the ears of infants are characteristic in such cases.

Diagnosis

The main method of diagnosis is the demonstration of Donovan bodies (Figure 63.7) in cellular material taken by scraping/impression smear/swab/crushing of pinched off tissue fragments on to a glass slide, or a tissue sample collected by biopsy. Either can be stained by Giemsa.

Management

- Azithromycin 1 g weekly or 500 mg daily.
- Ciprofloxacin 750 mg twice daily.
- Doxycycline 100 mg twice daily.
- Gentamicin (recommended by the US Centers for Disease Control and Prevention (CDC) as an adjunct to therapy in patients whose lesions do not respond in the first few days to other agents).

Figure 63.7 Granuloma inguinale: the histiocytes contain characteristic Donovan bodies (Warthin–Starry stain).

Image courtesy of W. Grayson MD, University of Witwatersrand, Johannesburg, South Africa.

Treatment should continue until the lesions have healed. Healing times vary considerably between patients. The CDC recommends a minimum of 3 weeks.

Gonorrhoea

In the UK, cases of uncomplicated gonorrhoea increased by 42% between 1998 and 2007. Gonorrhoea is the clinical disease resulting from infection with the Gram-negative diplococcus *N. gonorrhoeae*. The primary sites of infection are the mucous membranes of the urethra, endocervix, rectum, pharynx and conjunctiva.

Clinical features

- Infection at the endocervix is frequently asymptomatic (up to 50%).
- Increased or altered vaginal discharge is the most common symptom (up to 50%).
- Lower abdominal pain may be present (up to 25%).
- Urethral infection may cause dysuria (12%) but not frequency.
- Gonorrhoea is a rare cause of intermenstrual bleeding or menorrhagia.
- Rectal infection more frequently develops by transmucosal spread of infected genital secretions than from anal intercourse, and is usually asymptomatic.
- Pharyngeal infection is usually asymptomatic (>90%).
- *N. gonorrhoeae* may coexist with other pathogens, notably *T. vaginalis*, *Candida albicans* and *C. trachomatis*. If symptoms are present, they may be attributable to the coinfecting pathogen.
- Mucopurulent endocervical discharge and easily induced endocervical bleeding (<50%) (see Figure 63.8).
- Pelvic/lower abdominal tenderness (<5%).
- Commonly, no abnormal findings are present on examination.

Transluminal spread of *N. gonorrhoeae* may occur from the urethra or endocervix to involve the epididymis and prostate

Figure 63.8 Gonococcal cervicitis: the purulent endocervical discharge.

Figure 63.9 Gram-negative diplococci within polymorphonuclear leukocyte.

in men ($\leq 1\%$), and the endometrium and pelvic organs in women (probably <10%). Haematogenous dissemination may also occur from infected mucous membranes, resulting in skin lesions, arthralgia, arthritis and tenosynovitis. Disseminated gonococcal infection is uncommon (<1%).

Diagnosis

The diagnosis is established by the identification of *N. gonorrhoeae* at an infected site. Culture offers a readily available, specific, sensitive and cheap diagnostic test that readily allows confirmatory identification and antimicrobial susceptibility testing. Alternative tests include NAATs and nucleic acid hybridization tests. NAATs are more sensitive than culture and can also be used as diagnostic/screening tests on non-invasively collected specimens (urine and self-taken vaginal swabs). The sensitivity of culture may be less than 75% for endocervical swabs.

Rapid diagnostic tests can be performed to facilitate immediate diagnosis and treatment. Microscopy ($\times 1000$) of Gram-stained genital specimens allows direct visualization of *N. gonorrhoeae* as Gram-negative diplococci within polymorphonuclear leukocytes (Figure 63.9).

Management

Referral to a GUM department for management is strongly encouraged. Patients should be given a detailed explanation of their condition with particular emphasis on the long-term implications for the health of themselves and their partner(s). This should be reinforced with clear and accurate written information. Patients should be advised to avoid unprotected sexual intercourse until they and their partner(s) have completed treatment.

Screening for coincident STIs should be performed routinely in patients with or at risk of gonorrhoea.

Treatment

- Ceftriaxone 250 mg intramuscularly as a single dose.
- Cefixime 400 mg orally as a single dose.
- Spectinomycin 2 g intramuscularly as a single dose.

Surveillance data for 2004 show significant levels of *N. gonorrhoeae* resistance to penicillin (11.2%), tetracyclines (44.5%) and ciprofloxacin (14.1%) in the UK. Most resistant infections are acquired in the UK. The following alternative regimens may be used when an infection is known to be sensitive to these antimicrobials or where the regional prevalence of resistance to them is less than 5%.

- Ciprofloxacin 500 mg orally as a single dose.
- Ofloxacin 400 mg orally as a single dose.
- Ampicillin 2 g or 3 g plus probenecid 1 g orally as a single dose.
- Cefotaxime 500 mg intramuscularly as a single dose.
- Cefoxitin 2 g intramuscularly as a single dose plus probenecid 1 g orally.

Clinicians using alternative regimens are recommended to review local antimicrobial sensitivity testing regularly with microbiology colleagues.

Pregnancy and breast feeding

Pregnant women should not be treated with quinolone or tetracycline antimicrobials.

Recommended regimes

- Ceftriaxone 250 mg intramuscularly as a single dose.
- Cefixime 400 mg orally as a single dose.
- Spectinomycin 2 g intramuscularly as a single dose.
- Amoxycillin 3 g.
- Ampicillin 2 g or 3 g plus probenecid 1 g orally as a single dose, where regional prevalence of penicillin-resistant *N. gonorrhoeae* is $\leq 5\%$.

Screening for *C. trachomatis* should be performed routinely on adults with gonorrhoea, or treatment should be given to eradicate possible coinfection. Combining effective antimicrobial therapy against *C. trachomatis* with single-dose therapy for gonococcal infection is particularly appropriate when there is doubt that a patient will return for follow-up evaluation.

Chlamydia

Chlamydia can have serious side-effects, one of which is PID which can lead to infertility and ectopic pregnancy in

women. However, the disease can often be symptomless and therefore many people do not come forward to be tested.

New initiatives such as the National Chlamydia Screening Programme (NCSP) aim to control STIs through early detection and treatment. In particular, the NCSP targets sexually active people who might not normally have been tested for chlamydia. Nevertheless, there remains a vast number of people with chlamydia who do not know that they are infected.

Recent surveys of young women attending general practice clinics have reported prevalences of chlamydia of 8.1% among those under 20 years old and 5.2% among those aged 20–24 years. However, rates vary widely according to the setting in which the surveys take place. For example, among women under 20 years old, surveys have reported chlamydia prevalence of 17.3% in GUM clinics, 12.6% in antenatal clinics, 12.3% in TOP clinics, 10.7% in youth clinics, 10.0% in family planning clinics and 5.0% in the general population. In each setting, chlamydia prevalence is lower in higher age groups.

Between April 2005 and March 2006, the NCSP found chlamydia prevalences of 10.2% among women under 25 years old and 10.1% among men in the same age group. The NCSP uses a wide variety of non-GUM screening venues, including family planning clinics, general practice surgeries, prisons and military establishments. The rate peaked in the 16–19 years age group.

Aetiology

C. trachomatis is an obligate intracellular human pathogen. It is Gram-indeterminate (i.e. cannot be stained with the Gram stain), but structurally the organism is Gram-negative.

Chlamydia is the most common curable STI in the UK. It is frequently asymptomatic in both men and women, and ongoing transmission in the community is sustained by this unrecognized infection.

If untreated, infection may persist or resolve spontaneously. Two-thirds of sexual partners of chlamydia-positive individuals are also chlamydia-positive.

Clinical features

Chlamydia is asymptomatic in approximately 70% of infected women, but may cause any of the following: post-coital or intermenstrual bleeding, lower abdominal pain, purulent vaginal discharge, mucopurulent cervicitis (see Figure 63.10) and/or contact bleeding or dysuria. Rectal infections are usually asymptomatic, but may cause anal discharge and anorectal discomfort (proctitis).

Complications

In the absence of treatment, 10–40% of infected women will develop PID, with a significant proportion of these cases being asymptomatic or having mild, atypical symptoms. PID can result in tubal factor infertility, ectopic pregnancy and chronic pelvic pain. Other complications include Fitz-Hugh-Curtis syndrome (perihepatitis), transmission to neonate (neonatal conjunctivitis, pneumonia), epididymo-orchitis, adult conjunctivitis and sexually

Figure 63.10 Chlamydia cervicitis: a purulent discharge and inflamed follicles are seen.

Figure 63.11 Chlamydia perihepatitis violin-string adhesions are visible.

acquired reactive arthritis/Reiter's syndrome (more common in men).

Diagnosis

Nucleic acid amplification technique

Although the technology for diagnosing chlamydia continues to be a rapidly developing field, the standard of care for all cases, including medicolegal cases, is a NAAT. NAATs are more sensitive and specific than EIAs. The Department of Health has advised that the use of suboptimal EIAs is no longer appropriate, and has provided funding to support laboratories moving from EIAs to NAATs. In general, NAATs are 90–95% sensitive.

If a speculum examination is not possible, urine samples can be utilized. Variable sensitivities (65–100%) have been reported using an FCU specimen. Patients should hold their urine for at least 1 h before providing an FCU specimen.

Cell culture

Sensitivity of 60–80%, specificity of 100% and expertise is essential. The routine use of cell culture is not recommended due to high cost and low sensitivity.

Enzyme immunoassays

The sensitivity of the majority of EIAs is probably only 40–70% and their use is not recommended.

Management

Uncomplicated genital tract infection with *C. trachomatis* is not an indication for removal of an intrauterine contraceptive device.

Recommended regimens

- Doxycycline 100 mg twice daily for 7 days (contraindicated in pregnancy).
- Azithromycin 1 g orally in a single dose.

Alternative regimens

For use if either of the above treatments are contraindicated.

- Erythromycin 500 mg twice daily for 10–14 days.
- Ofloxacin 200 mg twice daily or 400 mg once daily for 7 days.

Erythromycin is less efficacious than either azithromycin or doxycycline. When taken four times daily, 20–25% of cases may experience side-effects sufficient to cause the patient to discontinue treatment. Oxytetracycline 500 mg twice daily for 10 days has also been shown to be effective.

Pregnancy and breast feeding

- Erythromycin 500 mg four times daily for 7 days.
- Erythromycin 500 mg twice daily for 14 days.
- Amoxicillin 500 mg three times daily for 7 days.
- Azithromycin 1 g stat.

A test of cure is not routinely recommended but should be performed in pregnancy or if non-compliance or re-exposure is suspected. It should be deferred for 5 weeks (6 weeks if azithromycin given) after treatment is completed.

Mycoplasma genitalium and *Ureaplasma urealyticum*

Mycoplasma (including *Ureaplasma urealyticum*) are small and have no cell wall. They are Gram negative and are difficult to culture. There are no commercially available tests. PCR is sometimes used for their detection.

Aetiology

Mucopurulent cervicitis is the female equivalent of non-gonococcal urethritis (NGU), 40% of cases being due to infection with *C. trachomatis*. *Mycoplasma genitalium* is an unproven cause of PID.

There are a number of uncertainties with NGU in men. Urethral inflammation can occur without a known pathogen being isolated in the majority of patients, even using more sensitive detection methods. The most common organisms implicated are *C. trachomatis* and *M. genitalium*, with the latter perhaps causing more symptoms. In 30–80% of cases with NGU, neither *C. trachomatis* nor *M. genitalium*

is detected. The exact role of ureaplasmas in NGU has been controversial due to the conflicting observations in clinical studies. Ureaplasmas are ubiquitous micro-organisms which have recently been divided into two biovars; *U. urealyticum* biovar 2 may account for 5–10% of cases of acute NGU. There is no clear indication for its treatment in women.

Management

The importance of evaluation and treatment of sexual partners is stressed in cases of NGU as *C. trachomatis* may be detected in the woman.

Treatment

Treatment as for *C. trachomatis* will eradicate *Mycoplasma* spp. including ureaplasma. However, it seems that resistant strains are emerging.

Genital Warts (Condylomata Accuminata)

Aetiology

The causative organism is the HPV (a DNA virus of the papovavirus group), especially types 6 and 11 (also 16, 18, 31, 33 and 35). Subclinical infection is extremely common, and trigger factors for an eruption of warts are not known. Occasionally in pregnancy, they may become very large and confluent. In men, similar giant and destructive warts may appear on the penis (Buschke–Löwenstein tumour) associated with types 6 and 11.

Cervical dysplasia and subsequent carcinoma is strongly associated with types 16 and 18; these types are associated with 70% of cervical cancers. Types 31, 33 and 35 represent the majority of other cases. Whilst cervical warts are seen in 10% of women with obvious warts elsewhere in the anogenital area, one-third will have evidence of wart infection on cytology or at colposcopic examination. In terms of risk for cervical cancer, the greatest threat seems to be from latent or subclinical infections with types 16 and 18.

Diagnosis

Between 1998 and 2007, the diagnosis of genital warts rose by 28%. The diagnosis is solely on clinical appearance. Warts in women are most commonly found on the vulva, but may appear anywhere in the anogenital area. They are usually painless. The presence of another STI is common (25%), and a full screen should be undertaken (see Figures 63.12 and 63.13).

Prevention

A decision by the UK Department of Health to introduce vaccination against HPV types 16 and 18 (Cervarix) was taken in October 2007. This decision follows the advice of the Joint Committee on Vaccination and Immunisation which, based on a detailed review of evidence surrounding HPV vaccination, recommended the routine vaccination of girls aged 12–13 years, recommended a catch-up programme

of girls under the age of 18 years, and acknowledged that the evidence that a catch-up programme for all women aged 18–25 years was unlikely to be cost-effective but could benefit some individual women. The Department of Health will consider this further.

Two vaccines, Cervarix and Gardasil, were competing for the contract. Both vaccines demonstrate highly effective protection against HPV 16 and 18, which are responsible for the majority of cases of cervical cancer. However, only one of the vaccines, Gardasil, protects against HPV types 6 and 11, as well as 16 and 18.

Treatment

Surface applications

Treatment choice depends on the morphology, number and distribution of warts, and patient preference. The evidence base to direct first- and second-line treatments is not strong. All treatments have significant failure and relapse rates. Treatment may involve discomfort and local skin reactions. Written information on the management of treatment side-effects is recommended.

Soft non-keratinized warts respond well to podophyllin, podophyllotoxin and trichloroacetic acid (TCA). Keratinized lesions are better treated with physical ablative methods such as cryotherapy, excision or electrocautery. Imiquimod may be suitable for both keratinized and non-keratinized warts. People with a small number of low-volume warts, irrespective of type, are best treated with ablative therapy from the outset.

Practitioners should consider developing a treatment algorithm or protocol. This has been shown to improve clinical outcome significantly.

Podophyllin is a non-standardized cytotoxic compound and is no longer recommended for use. It has been associated with severe local reactions. Serious systemic adverse events have occurred when used outside guidelines. Best practice described in the British National Formulary recommends supervised application in GUM clinics or general practice by trained nurses after screening for other STIs. Animal experiments indicate teratogenic and oncogenic properties. It should be avoided in pregnancy and not used on the cervix or anal canal. A 15–25% solution can be carefully applied to lesions, in clinic, once or twice weekly and washed off 4 h later.

Podophyllotoxin, a purified extract of podophyllin in the form of a 0.5% solution or 0.15% cream, is suitable for home treatment; supervision by medical staff is recommended for larger lesions. Podophyllotoxin has a license for the treatment of genital warts, but not extragenital lesions such as anal warts. Treatment cycles consist of twice-daily application for 3 days, followed by 4 days of rest for four to five cycles. Unprotected sexual contact should be avoided soon after application because of a possible irritant effect on the partner. Podophyllotoxin should be avoided in pregnancy.

TCA 80–90% solution is suitable for weekly application in a specialist clinic setting only. It acts as a caustic agent, resulting in cellular necrosis. An intense burning sensation may be experienced for 5–10 min after application. Ulceration penetrating into the dermis may occur, and it is

Figure 63.12 Vulval warts.
Courtesy of Dr I H Ahmed.

Figure 63.13 Cervical warts.

therefore not recommended for large-volume warts. TCA can be used at most anatomical sites.

TCA is extremely corrosive to the skin. Careful application and protection of the surrounding skin with petroleum jelly is recommended. A neutralizing agent (e.g. sodium bicarbonate) should always be available in case of excess application or spills.

5-Fluorouracil is a DNA antimetabolite, available in a 5% cream. Its use is limited by severe local side-effects, which may result in long-term problems such as neovascularization and vulval burning. It may be teratogenic and therefore should not be used in pregnancy. As satisfactory alternatives exist, this treatment is no longer recommended for the routine management of anogenital warts.

Various regimens have been described using interferons α , β and γ as creams and as intralesional or systemic injections. Their use is limited by expense, systemic side-effects and a variable response rate. Cyclical low-dose injection used as an adjunct to laser therapy has resulted in a lower relapse rate. Interferons are not recommended for routine management of anogenital warts and should only be used on expert advice.

Imiquimod is an immune response modifier. Available as a 5% cream, it induces a cytokine response when applied to skin infected with HPV. It is suitable for use on all external lesions, but is not recommended for use in pregnancy or

internally. It should be applied to lesions three times weekly and washed off 6–10 h later for up to 16 weeks. Unprotected sexual contact should be avoided soon after application because of a possible irritant effect on the partner. Latex condoms may be weakened if they come into contact with imiquimod.

Physical ablation

Removal of warts under local anaesthetic injection is particularly useful for pedunculated warts, and small numbers of keratinized warts at anatomically accessible sites. The use of an anaesthetic cream prior to injection is recommended. Treatment can be repeated as required. This is a good method of treatment for small numbers of warts and may be underused.

Cryotherapy using a liquid nitrogen spray or a cryoprobe causes cytolysis at the dermal epidermal junction resulting in necrosis. Treatment should be applied until a 'halo' of freezing has been established a few millimetres round the treated lesion. A freeze, thaw, freeze technique should be used and lesions held frozen for 10–30 s, depending upon size.

Electrocautery results in burning of the treatment site and surrounding tissue.

Hyfrecator acts by electrofulguration resulting in superficial charring and little dermal damage or, for deeper tissue penetration, electrodesiccation. This can be followed by curettage.

For monopolar surgery, different waveforms can be generated allowing desiccation, cutting or coagulation. This results in a cleaner cut and less damage to surrounding tissue (note: skin bridges should be left between treatment sites to aid healing and minimize scarring).

Laser treatment

The carbon dioxide laser is especially suitable for large-volume warts and can be used at difficult anatomical sites, such as the urethral meatus or anal canal.

All electrosurgical and laser techniques result in a plume of smoke which has been shown to contain HPV DNA, which may potentially cause infection of the respiratory tract in operating personnel. Therefore, masks should be worn and adequate extraction should be provided during these procedures.

The NHS Cervical Screening Programme does not recommend colposcopy in women with genital warts, including those with cervical lesions, unless there is diagnostic uncertainty or clinical concern. Additional cervical cytology is not recommended.

Pregnancy

Podophyllin, podophyllotoxin and 5-fluorouracil should be avoided because of possible teratogenic effects. Imiquimod is not approved for use in pregnancy. Treatment aims to minimize the number of lesions present at delivery to reduce exposure of the neonate to the virus. Potential problems for offspring are the development of laryngeal papillomatosis and anogenital warts. Very rarely, a CS is indicated because of obstruction of the vaginal outlet with warts or the presence of gross cervical warts. CS is not indicated to prevent

laryngeal papillomatosis/anogenital warts in the neonate, as both conditions are rare.

Immunosuppressed patients

People with impaired cell-mediated immunity (e.g. organ transplant patients or those with HIV infection) are likely to have poor treatment responses, increased relapse rates and an increased risk of developing anogenital intraepithelial neoplasia.

Molluscum Contagiosum

Aetiology and clinical features

Molluscum contagiosum is a benign viral skin infection most commonly seen in children. However, sexual contact in adults may lead to the appearance of lesions in the genital area. The condition is harmless.

Molluscum contagiosum is caused by a pox virus passed on by direct skin-to-skin contact, and may affect any part of the body. There is anecdotal evidence associating facial lesions with HIV-related immunodeficiency.

After an incubation period of 3–12 weeks, discrete, pearly, papular, smooth or umbilicated lesions appear (Figure 63.10). In immunocompetent individuals, the size of the lesions seldom exceeds 5 mm, and if untreated, there is usually spontaneous regression after several months. Secondary bacterial infection may result if lesions are scratched. In the immunocompromised, lesions may become large and exuberant, and secondary infection may be problematic. As other STIs may coexist, a full screen for these should be undertaken. HIV testing is recommended in patients presenting with facial lesions.

Treatment

Cryotherapy: liquid nitrogen should be applied until a halo of ice surrounds the lesion. Repeat applications may be necessary. The pearly core should be expressed either manually or using forceps, and the lesion can be pierced with an orange stick with or without the application of tincture of iodine or phenol. Curettage or diathermy may be carried out under local anaesthesia.

In patients with HIV infection, the introduction of highly active antiretroviral therapy may lead to resolution of lesions. Contact tracing of partners is unnecessary.

Viral Hepatitis

It should be noted that viral hepatitis is a notifiable disease in the UK, irrespective of the causative virus. Characteristics of the known hepatitis viruses are shown in Table 63.3.

Hepatitis A

Hepatitis A is caused by a picorna (RNA) virus, and is particularly common in areas of the world where sanitation is poor. It largely affects children, although 784 cases were reported in England and Wales in 2004.

Transmission can be oral (via food, water, close personal contact), by anal or digital-rectal contact, and via contaminated batches of factor VIII. The incubation period lasts 15–45 days. Most children and up to half of adults are asymptomatic or have mild non-specific symptoms with little or no jaundice. In clinical cases, there are two phases of symptoms: flu-like symptoms (malaise, myalgia, fatigue), often with right upper abdominal pain, which last for 3–10

Table 63.3 Characteristics of the known hepatitis viruses

Hepatitis virus	Transmission	Clinical features	Chronic infection
A	Faecal-oral	Silent in 90%	No
	Oroanal in homosexual men	Fulminant hepatitis very rare	
B	Parenteral	Silent in 90%	10% in adults
	Sexual	Children more often asymptomatic	90% in perinatal infection
	Vertical		
	Horizontal in endemic areas	Fulminant hepatitis in 1%	Can lead to: Chronic active hepatitis Cirrhosis Hepatocellular carcinoma
C	Parenteral	Silent in 95%	60%
	Sexual transmission uncommon	Fulminant hepatitis very rare	Chronic hepatitis Cirrhosis Hepatocellular carcinoma
D	Parenteral	Coinfection or superinfection with hepatitis B	60%
	Sexual		Effects as for HBV
	Only in those infected with HBV	Fulminant hepatitis 20%	
E	Faecal-oral	? limited to Africa/Asia	No
	Oroanal possible	Fulminant hepatitis common in pregnant women (10%)	

days; followed by anorexia, nausea and fatigue, which usually lasts for 1–3 weeks. It can persist for 12 or more weeks in a minority of patients who have cholestatic symptoms (itching and deep jaundice). Fever is not found in this phase. There may be jaundice with pale stools and dark urine. Liver enlargement/tenderness and signs of dehydration are also common.

Fifteen percent of patients may require hospital care, of whom one-quarter will have severe hepatitis (prothrombin time >3 s prolonged, or bilirubin >170 mmol/l). The infection does not have any teratogenic effects but there is an increased rate of miscarriage and premature labour, proportional to the severity of the illness. There have been case reports of possible vertical transmission.

Serology

Measurement of specific IgM (HAV-IgM) is best and remains positive for 6 months or more. HAV-IgG does not distinguish between current or past infection, and may remain positive for life.

Screening should be undertaken for other STIs in cases of sexually acquired hepatitis or if otherwise appropriate.

Hepatitis A vaccine may be given up to 14 days after exposure, providing exposure was within the infectious period of the source case (during the prodromal illness or first week of jaundice).

Hepatitis B

Hepatitis B is caused by an hepadna (DNA) virus. It is endemic worldwide with very high carriage rates (up to 20%), particularly in South and East Asia, but also in Southern Europe, Central and South America, Africa and Eastern Europe. In the UK, carriage varies from 0.01–0.04% in blood donors to more than 1% in intravenous drug users and homosexual men. In 2003, 1151 cases were notified in England and Wales. There are eight distinct genotypes (A–H) which vary in geographical distribution, pathogenicity and treatment susceptibility.

Transmission occurs in immune men who have sex with men and correlates with multiple partners, unprotected anal sex and oroanal sex. Transmission also occurs after heterosexual contact (e.g. 18% infection rates for regular partners of patients with acute hepatitis B). Sex workers are also at higher risk, as are intravenous drug users. Vertical transmis-

sion of infection occurs in 90% of pregnancies where the mother is hepatitis B e antigen positive, and in approximately 10% of surface-antigen-positive, e-antigen-negative mothers. Most (>90%) infected infants become chronic carriers. Infants born to infectious mothers are vaccinated from birth, usually in combination with hepatitis-B-specific immunoglobulin 200 iu intramuscularly; this reduces vertical transmission by 90%.

Asymptomatic infection is also found in 10–50% of adults in the acute phase and is especially likely in those with HIV coinfection. Chronic carriers are usually asymptomatic but may have fatigue or loss of appetite. The prodromal and icteric phases are very similar to hepatitis A, but may be more severe and prolonged.

Fulminant hepatitis occurs in less than 1% of symptomatic cases but carries a worse prognosis than that caused by hepatitis A. Concurrent hepatitis C infection can lead to fulminant hepatitis, more aggressive chronic hepatitis and increased risk of liver cancer.

If chronic infection occurs (as it does in 5–10% of symptomatic cases, higher in the immunocompromised), there are often no physical signs. After many years of infection, depending on the severity and duration, there may be signs of chronic liver disease including spider naevi, finger clubbing, jaundice and hepatosplenomegaly, and in severe cases, thin skin, bruising, ascites, liver flap and encephalopathy.

Mortality is less than 1% for acute cases. Between 10% and 50% of chronic carriers will develop cirrhosis, leading to premature death in approximately half. Ten percent or more of cirrhotic patients will progress to liver cancer.

Concurrent HIV infection increases the risk of progression to cirrhosis and death.

The serology profiles are shown in Table 63.4.

Patients should be advised to avoid unprotected sexual intercourse until they have become non-infectious or their partners have been successfully vaccinated. They should have a full STI screen. Further management is undertaken by hepatologists or physicians with experience in the management of hepatitis.

Hepatitis B testing in asymptomatic patients should be considered in men who have sex with men, sex workers (of either sex), injecting drug users, HIV-positive patients, sexual assault victims, people from countries where hepatitis B is common, and women attending antenatal clinics. If patients are non-immune, vaccination should be considered. If

Table 63.4 Hepatitis B serology: interpretation of common results

	HBsAg	Anti HBs	Anti HBc	Anti HBc-IgM	HBeAg	Anti HBe

Acute infection (late)	+	–	+	+	+	–
Chronic infection (high infectivity)	+	–	+	±	+	–
Chronic infection (low infectivity)	+	–	+	–	–	+

Source: Gibson R 2004 Viral hepatitis. In: Adler M, Cowan F, French P, Mitchell H, Richens J (eds) ABC of Sexually Transmitted Infections, 5th edn. BMJ Books, London.

patients are found to be chronic carriers, referral for therapy should be considered. The simplest initial screening test in someone who is unvaccinated or is of unknown infection status is anti-hepatitis B core antigen, with the addition of other tests as necessary. Some also screen for hepatitis B surface antigen initially.

Hepatitis D

This is caused by a defective RNA virus which cannot thrive in the absence of chronic hepatitis B. In such patients, the clinical course is severe. Simultaneous coinoculation with hepatitis B usually resolves. Hepatitis D may be acquired sexually but the population at greatest risk is intravenous drug users. Diagnosis is by antibody assay. The management belongs properly in the hands of hepatologists.

Hepatitis C

Hepatitis C is another RNA virus causing chronic hepatitis. It may be transmitted sexually but this has proved inefficient with less than 5% of long-term partners becoming infected. Injecting drug users are the highest risk group. Vertical transmission is rare but the risk increases if there is coexisting HIV infection. Exposure to the virus from contaminated blood and blood products used in health care has been eliminated. There is no vaccine. Diagnosis is on serology; however, an antibody response may be delayed by up to 4 weeks so the test may need repeating. The management is undertaken by hepatologists and the virus may be cleared by combination therapy with interferon and ribavirin.

Hepatitis E

Hepatitis E is an RNA virus which usually causes an acute and self-limiting infection. It is spread by orofaecal transmission. It has a high mortality rate in pregnant women (17–30%). It causes sporadic cases and waterborne epidemics in the Indian subcontinent, South-east and Central Asia, Africa and North America. Cases in the UK are usually only seen in travellers returning from these areas. It is detected on serology.

Vaginal Infections

The acidic milieu of the vagina (pH 4.5) is maintained by lactobacilli (Döderlein's) which accounts for 95% of the

bacteria found in the normal vaginal flora. This inhibits the overgrowth of other vaginal commensals under normal conditions. The substrate for lactic acid production is glycogen in the vaginal squamous cells, which is itself dependent upon the presence of oestrogen. Thus, prepubertal girls, pregnant women and postmenopausal women may have increased vaginal pH. Another more direct cause of increasing vaginal pH is the practice of douching, which should be discouraged. Smokers also have increased vaginal pH. The differential diagnoses of the common causes of vaginal discharge are summarized in Table 63.5.

Bacterial vaginosis

An elevation in pH may allow other commensals of the vagina to replicate in greater quantity and this may result in bacterial vaginosis. This is a common cause of attendance at GUM clinics, as it is mistaken by the woman as a possible STI, which it is not. The prevalence in the UK is of the order of 15% but it may be under-reported.

Bacterial vaginosis is characterized by an overgrowth of predominantly anaerobic organisms (*Gardnerella vaginalis*, *Prevotella* spp., *Mycoplasma hominis*, *Mobiluncus* spp.) in the vagina, leading to replacement of lactobacilli and an increase in pH from less than 4.5 to as high as 7.0.

Clinical features and complications

There is an offensive fishy smelling, thin, white vaginal discharge not associated with soreness, itching or irritation. However, in many women (approximately 50%), bacterial vaginosis is asymptomatic (see Figure 63.14).

The prevalence of bacterial vaginosis is high in women with PID, and it is common in some populations of women undergoing elective TOP, and associated with post-TOP endometritis and PID. In pregnancy, bacterial vaginosis is associated with late miscarriage, preterm birth, preterm premature rupture of the membranes and postpartum endometritis.

Diagnosis

Two approaches are available.

Amsel criteria

At least three of the following four criteria need to be present for the diagnosis to be confirmed.

Table 63.5 Differential diagnosis of the common causes of vaginal discharge

Symptoms and signs	Candidiasis	Bacterial vaginosis	Trichomoniasis	Cervicitis
Itching or soreness	++	–	+++	–
Smell	May be yeasty	Offensive, fishy	May be offensive	–
Colour	White	White or yellow	Yellow or green	Clear or coloured
Consistency	Curdy	Thin, homogeneous	Thin, homogeneous	Mucoid
pH	<4.5	4.5–7.0	4.5–7.0	<4.5
Confirmed by	Microscopy and culture	Microscopy	Microscopy and culture	Microscopy, tests for chlamydia and gonorrhoea

Figure 63.14 Bacterial vaginosis.

- Thin, white, homogeneous discharge.
- Clue cells (Figure 63.15) on microscopy of wet mount.
- pH of vaginal fluid >4.5.
- Release of a fishy odour on adding alkali (10% potassium hydroxide).

Gram-stained vaginal smear

This is evaluated with the Hay (note: not the author)/Ison criteria or the Nugent criteria. The Hay/Ison criteria are defined as follows.

- Grade 1 (normal): lactobacillus morphotypes predominate.
- Grade 2 (intermediate): mixed flora with some lactobacilli present, but gardnerella or mobiluncus morphotypes also present.

- Grade 3 (bacterial vaginosis): predominantly gardnerella and/or mobiluncus morphotypes. Few or absent lactobacilli.

Management

Patients should be advised to avoid vaginal douching, use of shower gel, and use of antiseptic agents or shampoo in the bath. Treatment is indicated for symptomatic women, and women undergoing some surgical procedures and women who do not volunteer symptoms may elect to take treatment if offered. They may report a beneficial change in their discharge following treatment. Metronidazole 400–500 mg twice daily for 5–7 days or 2 g as a single dose is most commonly prescribed. Alternative regimens are intravaginal metronidazole gel (0.75%) once daily for 5 days, intravaginal clindamycin cream (2%) once daily for 7 days, clindamycin 300 mg twice daily for 7 days or tinidazole 2 g single dose. All these treatments have been shown to achieve cure rates of 70–80% after 4 weeks.

Clindamycin cream can weaken condoms, which should not be used during such treatment. Symptomatic pregnant women should be treated as above. A test of cure is not required if symptoms resolve.

There are few published studies evaluating the optimal approach to women with frequent recurrences of bacterial vaginosis. Possible approaches being evaluated include metronidazole gel 0.75% twice weekly for 4–6 months to decrease symptoms, after an initial treatment daily for 10 days, or metronidazole orally 400 mg twice daily for 3 days at the start and end of menstruation, combined with fluconazole 150 mg as a single dose if there is also a history of candidiasis.

Small studies of live yoghurt or *Lactobacillus acidophilus* have not demonstrated benefit.

Candidiasis

This is a common non-STI cause of infective vaginal discharge that will affect approximately 75% of women at some stage during their reproductive life.

Aetiology and clinical features

The causative agent is *C. albicans* in 80–92% of cases. Non-*albicans* species (e.g. *C. glabrata*, *C. tropicalis*, *C. krusei*, *C. parapsilosis* and *Saccharomyces cerevisiae*) account for the remainder of cases.

Vulval itch and/or soreness, vaginal discharge (typically curdy but may be thin, non-offensive), superficial dyspareunia and external dysuria are common complaints. There may be erythema, fissuring, oedema, satellite lesions and excoriation. None of these symptoms or signs are pathognomonic for vulvovaginal candidiasis. Many women may have other conditions, such as dermatitis, allergic reactions and lichen sclerosus. In addition, symptoms/signs are no guide to species (see Figure 63.16).

Ten to twenty percent of women of reproductive age may be colonized with *Candida* spp. but have no clinical signs or symptoms. These women do not require treatment.

Figure 63.16 *Candida* vaginitis: note the thick adherent discharge.

Diagnosis

In the context of comprehensive sexual health services, routine microscopy and culture is the standard. A vaginal swab should be taken from the anterior fornix for a Gram or wet film examination. This should be directly plated to solid fungal media. Speciation is essential if complicated disease is present.

Since all topical and oral azole therapies give a clinical and mycological cure rate of over 80% in uncomplicated acute vulvovaginal candidiasis, choice is a matter of personal preference, availability and affordability. Topical azole therapies can cause vulvovaginal irritation, and this should be considered if symptoms worsen or persist. In pregnancy, oral azole therapy is contraindicated.

Recurrent vulvovaginal candidiasis (occurs in 5% of women of reproductive age) is defined as at least four documented episodes of symptomatic vulvovaginal candidiasis annually. Positive microscopy or a moderate/heavy growth of *C. albicans* should be documented on at least two occasions when symptomatic.

Candidiasis is usually caused by host factors (e.g. uncontrolled diabetes mellitus, immunosuppression, hyperoestrogenaemia (e.g. hormone replacement therapy) and the combined oral contraceptive pill) rather than a more virulent strain or reintroduction of the organism to the genital tract. Occasionally, it is due to disturbance of vaginal flora, such as through use of broad-spectrum antibiotics.

Vulval emollients may give symptomatic relief. High-oestrogen contraceptives should be avoided, or consideration given to changing to a non-oestrogenic form of contraception.

Fluconazole may be given to suppress recurrences in regimes up to and including once weekly for 6 months. Topical imidazole therapy can be increased to 10–14 days according to symptomatic response.

Figure 63.17 *Trichomonas vaginalis*.

In general, longer courses may be needed for non-albicans infection although there are no data on optimum duration; 2 weeks is suggested. There is no comparative evidence for different treatments. A suggested alternative is nystatin (a polyene); these pessaries are the only licensed alternative to azole therapy, and are therefore the usual first-line treatment for non-albicans infection.

Trichomoniasis

Aetiology and clinical features

T. vaginalis is a flagellate protozoan (Figure 63.17). In women, the organism is found in the vagina, urethra and paraurethral glands. While the urinary tract is the sole site of infection in less than 5% of cases, urethral infection is present in 90% of episodes. In adults, transmission is almost exclusively sexual. Due to site specificity, infection can only follow intravaginal or intraurethral inoculation of the organism.

Ten to fifty percent of infected women are asymptomatic. In those with symptoms, these include vaginal discharge, vulval itching, dysuria or offensive odour. Occasionally, the presenting complaint is low abdominal discomfort.

Vaginal discharge occurs in up to 70% of cases, varying in consistency from thin and scanty to profuse and thick; the classical frothy yellow discharge occurs in 10–30% of women. Approximately 2% of patients will have strawberry cervix appearance to the naked eye. Higher rates are seen on colposcopic examination. No abnormalities will be seen in 5–15% of women on examination.

There is increasing evidence that *T. vaginalis* infection can have a detrimental outcome on pregnancy, and is associated with preterm delivery and low birth weight. However, further research is needed to confirm causality. Moreover, recent trials have found that treatment does not improve pregnancy outcome, and may be harmful. Screening of asymptomatic individuals for *T. vaginalis* infection is therefore not currently recommended (see Figure 63.18A,B).

Diagnosis

Direct observation by wet mount or acridine orange staining is approximately 70% sensitive compared with culture in

Figure 63.18 Trichomonas: (A) grey watery discharge, (B) strawberry cervix with petechial haemorrhage.

females. Microscopy for *T. vaginalis* should be performed as soon as possible after the sample is taken, as motility diminishes with time.

Culture techniques are still regarded as the most sensitive and specific. Culture media vary in efficiency, but Diamond's TYM medium (or modified version) is among the best.

PCR-based diagnostic tests have been developed recently, and sensitivities and specificities approaching 100% have been reported. No PCR assay for *T. vaginalis* is currently on the market.

Trichomonads are sometimes reported on cervical cytology; however, a meta-analysis has shown that while it has good specificity, the weighted mean sensitivity was only 58%. In such cases, it is prudent to confirm the diagnosis, preferably by culture of vaginal secretions.

Management and treatment

Sexual partner(s) should be treated simultaneously. Patients should be advised to avoid sexual intercourse (including oral sex) until they and their partner(s) have completed treatment and follow-up.

Screening for coexistent STIs should be undertaken in both men and women.

The frequency of infection of the urethra and paraurethral glands in females dictates that systemic chemotherapy should be given to effect a permanent cure. Most strains of *T. vaginalis* are highly susceptible to metronidazole and related drugs (approximately 95% cure rate). There is a spontaneous cure rate of the order of 20–25%.

Recommended regimens

- Metronidazole 2 g orally in a single dose.
- Metronidazole 400–500 mg twice daily for 5–7 days — most commonly prescribed with tinidazole

2 g orally in a single dose as an alternative regimen.

Patients should be advised not to take alcohol for the duration of treatment and for at least 48 h afterwards because of the possibility of a disulfiram-like (Antabuse effect) reaction.

The British National Formulary advises against high-dose regimens in pregnancy.

Patients who fail to respond to the first course of treatment often respond to a repeat course of standard treatment. Current partners should be screened for the full range of STIs and treated for *T. vaginalis* irrespective of the results of investigations.

Trichomonas infection may be acquired perinatally and occurs in approximately 5% of babies born to infected mothers. Infection beyond the first year of life should suggest sexual contact.

Ectoparasitic Infestations

Pediculosis pubis (Phthirus pubis)

Aetiology and clinical features

The crab louse *Phthirus pubis* (Figure 63.19) is transmitted by close body contact. The incubation period is usually between 5 days and several weeks, although occasional individuals appear to have more prolonged, asymptomatic infestation.

Adult lice infest coarse hairs of the pubic area, body hair and, rarely, eyebrows and eyelashes. Eggs (nits) are laid which adhere to the hairs. There may be no symptoms or there may be itching due to hypersensitivity to feeding lice. Blue macules (maculae caeruleae) may be visible at feeding sites.

Figure 63.19 The crab louse: *Phthirus pubis* or *Pediculosis pubis*.
Source: World Health Organization.

Diagnosis

Diagnosis is based on finding adult lice and/or eggs. Examination under light microscopy can confirm the morphology if necessary.

Management and treatment

Patients should be advised to avoid close body contact until they and their partner(s) have completed treatment and follow-up. A full screen for other STIs should be undertaken.

Lotions are likely to be more effective than shampoos, and should be applied to all body hair including the beard and moustache if necessary. A second application after 3–7 days is advised.

Agents used

- Malathion 0.5%: apply to dry hair and wash out after at least 2 h, and preferably 12 h (i.e. overnight).
- Permethrin 1% cream rinse: apply to damp hair and wash out after 10 min.
- Phenothrin 0.2%: apply to dry hair and wash out after 2 h.
- Carbaryl 0.5 and 1% (unlicensed indication): apply to dry hair and wash out 12 h later.

Infestation of eyelashes can be treated with permethrin 1% lotion, keeping the eyes closed during the 10-min application. Alternatively, an inert ophthalmic ointment with a white or yellow paraffin base such as simple eye ointment BP may be applied to the eyelashes twice daily for 8–10 days. This works by suffocating lice and avoids any risk of eye irritation by topical insecticide.

Permethrin is safe during pregnancy and breast feeding.

Current sexual partners should be examined and treated. Contact tracing of partners from the previous 3 months should be undertaken. Patients should be re-examined for absence of lice after 1 week. Treatment failures should be given an alternative from the above list. It should be

explained to patients that dead nits may remain adherent to hairs. This does not imply treatment failure, and the nits can be removed with a comb designed specifically for the purpose.

Scabies

Aetiology and clinical features

The infestation is caused by the mite *Sarcoptes scabiei*. Mites burrow into the skin where they lay eggs, the resulting offspring crawl out on to the skin and make new burrows. Any part of the body may be affected, and transmission is by skin-to-skin contact. The absorption of mite excrement into skin capillaries generates a hypersensitivity reaction. The main symptom, which may take 4–6 weeks to develop, is generalized itch, especially at night.

Characteristic silvery lines may be seen in the skin where mites have burrowed. Classic sites include the interdigital folds, the wrists, elbows and around the nipples in women. Papules or nodules that may result from itching often affect the genital area. In HIV infection, crusted lesions that teem with mites (Norwegian scabies) pose a significant risk of transmission to others.

Secondary infection of the skin lesions can occur following repeated scratching. The clinical appearance is usually typical, but there may be diagnostic confusion with other itching conditions such as eczema. Scrapings taken from burrows may be examined under light microscopy to reveal mites.

Management and treatment

Patients should be advised to avoid close body contact until they and their partner(s) have completed treatment. A full screen for other STIs should be undertaken, as there is anecdotal evidence of rates of infection similar to other patients attending GUM clinics.

Two topical treatments are recommended in the UK. Benzyl benzoate is regarded as too irritant, and crotamiton is ineffective compared with the recommended options which are Permethrin 5% cream or Malathion 0.5% aqueous lotion. These should be applied to the whole body from the neck downwards, and washed off after 12 h, usually overnight. Itch may persist for several weeks. Application of crotamiton cream may give symptomatic relief, and antihistamines may also be helpful. Potentially contaminated clothes and bedding should be washed at a high temperature (>50°C) if possible. Mites separated from the human host die within 72 h. Permethrin is safe during pregnancy and breast feeding.

Current sexual partners as well as other members of the household should be examined and treated. An arbitrary time span is for contacts from the previous 2 months to be traced. No clear evidence exists regarding optimal follow-up. The appearance of new burrows at any stage following treatment is indicative of a need for further therapy, although in reinfection, symptoms of pruritus may recur before typical burrows have developed. Pruritus persisting for more than 2 weeks after treatment may reflect treatment failure, reinfection or drug allergy to antiscabietics.

KEY POINTS

1. STIs are on the increase in the UK and are found across the whole spectrum of society.
2. Many people with STIs have subclinical infections with few symptoms.
3. Aside from the morbidity that STIs can cause, they are often coassociated and increase the potential for HIV infection.
4. The presence of one STI should prompt screening for others.
5. New, more sensitive tests based on nucleic acid detection techniques have been introduced in the past 10 years to aid speed and accuracy of diagnosis.
6. GUM departments should be involved to screen, ensure a test of cure (when necessary) and organize contact tracing.
7. A new screening programme for chlamydia has been instigated by the UK Department of Health. *C. trachomatis* is now the most prevalent STI in the UK.
8. Screening for syphilis in pregnant women is becoming increasingly pertinent as the incidence of new diagnoses has increased dramatically and remains cost-effective.
9. A vaccination programme against the wart virus serotypes most commonly associated with development of cervical cancer has been introduced by the UK Department of Health.
10. BASSH has been very active in producing national guidelines for the management of STIs over the past 10 years. Local protocols should reflect and refer to those guidelines for which auditable standards are available.

PREGNANCY CONTROL	984		

Introduction

Over 50% of all individuals infected with human immunodeficiency virus (HIV) are women (Joint United Nations Programme on HIV/AIDS 2008). Whilst HIV itself has no major specific gynaecological manifestations, it does impinge heavily on gynaecological practice. Some problems, such as recurrent vaginal candidiasis, florid human papilloma virus (HPV) infection and an increased prevalence of cervical intraepithelial neoplasia (CIN), are the result of increasing immunosuppression. However, many of the current gynaecological issues encountered in the HIV-infected woman, such as contraception, pregnancy and infertility management, are a result of dramatic improvements in available therapy and consequent improvement in overall prognosis.

Background

HIV is a retrovirus, a double-stranded RNA virus that uses the enzyme reverse transcriptase to form DNA and integrate itself into the host cell which then becomes a 'factory' for producing more virus (Figure 64.1). T-cell helper lymphocytes bearing the CD4 receptor, pivotal in the cell-mediated immune response, are targeted by the virus and destroyed.

The natural history of HIV is characterized by gradual clinical deterioration. A decreasing CD4 lymphocyte count and increasing levels of virus in the blood plasma are used in monitoring the course of the disease in conjunction with clinical events. Most evidence regarding the natural history of HIV infection is based on studies of men, and it is not clear whether this is directly applicable to women. Seroconversion, the development of antibodies to HIV detectable in the serum, usually occurs soon after infection and the new fourth-generation combined antigen-antibody assays enable

an accurate diagnosis to be made within 14 days of infection. Up to 50% of patients may experience an acute infectious mononucleosis-like syndrome, the 'primary HIV infection', at the time of seroconversion with rash, fever, myalgia, arthralgia, headache, diarrhoea and sore throat.

Acquired immunodeficiency syndrome (AIDS) diagnoses represent a range of disorders including infection and neoplasia (Centers for Disease Control and Prevention 1992). The risk of severe immunodeficiency and AIDS increases with the duration of infection. The median time to development of AIDS in untreated HIV-positive patients is approximately 7–10 years. Prior to the development of AIDS, patients may either be asymptomatic or experience persistent generalized lymphadenopathy (enlarged lymph nodes in at least two extrainguinal sites, lasting for at least 3 months and not attributable to any other cause) or symptoms due to immune deterioration that has many manifestations.

Early in the epidemic, before the widespread use of antiretroviral therapy and prophylaxis against opportunistic infections, median survival after an AIDS-defining illness was 11 months. Early studies did suggest a worse prognosis for women with HIV, although this finding is likely to have been the result of inequalities in access to care rather than biological gender differences. The course of infection varies between individuals, and there are 'long-term non-progressors' who are infected for long periods of time but manifest no evidence of immunocompromise in terms of either peripheral CD4 count or clinically detectable disease.

Treatment

In the last decade, widespread use of combination antiretroviral therapy in Europe and the USA has substantially reduced the rate of progression to AIDS and improved survival. Deaths that included AIDS-related causes decreased

Figure 64.1 HIV lifecycle and action of antiretroviral agents.

from 3.79/100 person-years in 1996 to 0.32/100 person-years in 2004 (Palella et al 2006). Six classes of antiretroviral agents are now available — nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors, integrase inhibitors, entry inhibitors (or fusion inhibitors) and maturation inhibitors — all of which interrupt the virus' lifecycle (Figure 64.1). The aim of highly active antiretroviral therapy (HAART), a combination of three or more drugs usually including a protease inhibitor or an NNRTI, is to slow progression of the disease by reducing viral load and thus increasing CD4 count. The British HIV Association has published guidelines on when to start HAART (British HIV Association Treatment Guidelines Writing Group 2008). Efavirenz should be considered as the first-line therapy in all patients, unless the patient is trying to conceive and has primary NRTI or NNRTI resistance. After treatment is commenced, viral load should reach 'undetectable' levels, usually less than 50 copies/ml. The CD4 count should rise, with levels below $200 \times 10^6/l$ representing a significant risk of development of an opportunistic infection. Compliance with HAART regimes needs to be in excess of 95% (Paterson et al 2000) for treatment to be effective and to reduce the chance of emergence of resistant virus.

Transmission

HIV has been isolated in blood, seminal fluid, vaginal secretions, cerebrospinal fluid, saliva, lacrimal secretions and breast milk. The concentration in different body fluids varies.

The virus may be transmitted by sexual intercourse, intravenous drug use, transfusion, occupational exposure and vertically from mother to child. The predominant route of infection worldwide is heterosexual sex and, with the great majority of the affected population being in their reproductive years, vertical transmission is an increasing problem. Proper use of condoms is known to greatly reduce the risk of transmission (Heikinheimo and L  hteenm  ki 2009). Male-to-female transmission is more efficient than female-to-male transmission, with the mucous membrane of the vagina being more permeable and the surface area being greater, although a partner receptive to anal intercourse is at greatest risk. It is difficult to quantify the risk of sexual transmission 'per act' as a constellation of factors are involved, although higher levels of viral load and intercurrent sexually transmitted infection (Wasserheit 1992), particularly ulcerative conditions, in either partner make transmission more likely. Use of barrier methods should also be encouraged in concordant HIV-positive couples to reduce the risk of transmission of resistant virus.

Although transmission of HIV between women who have sex with women (Monzon and Capellan 1987) is very rare, cases have occurred. Use of dental dams (latex barriers) should be encouraged to reduce oral contact with vaginal secretions, and shared sex toys should be cleaned appropriately. Salivary hypotonicity is thought to inactivate HIV-infected lymphocytes, and hence salivary transmission is almost certainly very rare. Oral sex, although less risky than vaginal or anal sex, may result in transmission and this may, in part, be the result of the isotonic nature of seminal fluid

overcoming the inactivation of infected cells by hypotonic saliva.

In 2007, approximately 370,000 children under 15 years of age became infected with HIV, mainly through mother-to-child transmission (MTCT). Approximately 90% of infections due to MTCT occurred in Africa where AIDS is beginning to reverse decades of steady progress in child survival. In high-income countries, MTCT has been virtually eliminated thanks to effective voluntary testing and counseling, access to antiretroviral therapy, safe delivery practices, and the widespread availability and safe use of breast-milk substitutes.

HIV testing

HIV testing should be performed with the woman's consent, and needs only a pretest discussion and consent by a trained healthcare worker. Medical care and support for those diagnosed HIV positive should be arranged immediately after diagnosis. As with all medical care, patient confidentiality should be respected.

There are two methods in routine practice for testing for HIV: screening assay, where blood is sent to the laboratory for testing, or a rapid point of care test (UK National Guidelines for HIV Testing 2008). The recommended first-line assay is one which tests for HIV antibody and p24 antigen simultaneously. These are termed 'fourth-generation assays' and have the advantage of reducing the time between the infection and testing HIV positive to 1 month; this is 1–2 weeks earlier than with sensitive third-generation (antibody-only detection) assays. HIV RNA quantitative assays (viral load tests) are not recommended as screening assays because of the possibility of false-positive results, and because they only have a marginal advantage over the fourth-generation assays for the detection of primary infection. Laboratories undertaking screening tests should be able to confirm antibody and antigen/RNA. There is a requirement for three independent assays able to distinguish HIV-1 from HIV-2. These tests could be provided within the primary testing laboratory or by a referral laboratory. All new HIV diagnoses should be made following appropriate confirmatory assays and testing a second sample. Testing including confirmation should follow the standards laid out by the Health Protection Agency (2007).

Point of care tests offer the advantage of a result from either a finger prick or a mouth swab sample within minutes. They have advantages of ease of use when venepuncture is not possible (e.g. outside conventional healthcare settings) and where a delay in obtaining results is a disadvantage, but these must be weighed against the disadvantages of a test which has reduced specificity and reduced sensitivity compared with current fourth-generation assays. Point of care tests are therefore recommended in the following settings:

- clinical settings where rapid turnaround of testing results is desirable;
- community testing sites;
- urgent source testing in cases of exposure incidents; and
- circumstances where venepuncture is refused.

Although a cure for HIV remains elusive, the advent of effective treatment has resulted in a significantly more

optimistic outlook for infected patients. There are clear advantages to knowledge of HIV status, not only in terms of accessing medical monitoring and treatment but also regarding protection of sexual partners and reduction of risk of MTCT. Antenatal testing, previously only offered to women deemed at high risk of infection, is now offered universally as part of routine investigations offered to women in early pregnancy (see below).

The HIV epidemic

More than 25 million people have died of AIDS since 1981. Globally, there were an estimated 33 million people living with HIV in 2007. The annual number of new HIV infections declined from 3 million in 2001 to 2.7 million in 2007. Overall, 2 million people died due to AIDS in 2007, compared with an estimate of 1.7 million in 2001. While the percentage of people living with AIDS has stabilized since 2000, the overall number of people living with HIV has increased steadily as new infections occur each year, HIV treatments extend life and new infections still outnumber AIDS deaths. Southern Africa continues to bear a disproportionate share of the global burden of HIV; 35% of HIV infections and 38% of AIDS deaths occurred in that subregion in 2007. Sub-Saharan Africa is home to 67% of people living with HIV (Joint United Nations Programme on HIV/AIDS 2008).

In 2007, there were an estimated 77,400 persons living with HIV (both diagnosed and undiagnosed), equivalent to 127 persons living with HIV per 100,000 population in the UK (170 per 100,000 men and 84 per 100,000 women). Among 73,300 persons aged 15–59 years living with HIV, 28% are unaware of their infection. A total of 7734 persons (4887 men and 2846 women) were diagnosed with HIV in 2007; a rate of 16 new diagnoses per 100,000 men and nine per 100,000 women. Seventy per cent of the 56,556 persons seen for HIV care were receiving antiretroviral therapy. However, almost one in five HIV-infected persons with severe immunosuppression were not on treatment (Health Protection Agency 2008).

Gynaecological Symptomatology

Women with HIV experience the same range of gynaecological symptoms as their HIV-negative counterparts. As with any woman, it is important that she is treated with compassion and understanding, and that investigation and treatment of gynaecological problems are thorough and tailored to the woman's individual situation. Problems that might, in the past, not have been of real significance to women coping with a terminal disease are now increasingly relevant, with women realistically expecting a near-normal lifespan. By and large, HIV status should not alter treatments available to women, although there are a few caveats to this which are discussed below. As with all medical care, good communication with accurate information is essential.

Menstrual cycle

Intuitively, it might be expected that women with HIV, as with any chronic disease, might experience menstrual

irregularity or periods of amenorrhoea, perhaps associated with weight loss or deteriorating health. It is certainly true that associated medical problems such as thrombocytopenia may result in menorrhagia, while liver or renal insufficiency may cause amenorrhoea.

While, anecdotally, women with HIV are often said to suffer menstrual disturbance, evidence to support an effect of HIV itself on menstrual pattern is sparse and often conflicting. The consensus is that there is no direct effect of HIV on menstrual pattern, although increasingly disturbed cycles may occur in women with advanced HIV infection who are severely immunocompromised (CD4 count <200) (Harlow et al 2000).

The clinical impression of a high prevalence of an abnormal bleeding pattern may be biased in two ways:

- women with HIV routinely see their doctors at frequent (usually 3-monthly) intervals and so have more opportunity to consult their physicians regarding any perceived problem; and
- the majority of infected women are of Black African origin and are therefore more likely to have fibroids.

HIV shedding into cervical fluid is lowest in the follicular phase and peaks during menstruation (Reichelderfer et al 2000), with obvious implications for sexual transmission.

Little information is available on endocrine function in females with HIV. In men, no striking differences have been found when the men are well, but hypogonadotrophic hypogonadism has been reported as a common feature in those who have AIDS. It has been suggested that this may relate to chronic ill health and weight loss rather than to HIV infection itself.

In general, menstrual abnormality should be investigated and treated as in the HIV-negative population, although caution should be exercised when intercurrent disease or treatment affects liver function and may alter metabolism of drug therapy or hormones. In severely immunocompromised patients, abnormal uterine bleeding may be a result of an HIV-related condition, opportunistic infection or neoplasm, and investigation should be tailored appropriately.

Vaginitis

Recurrent vaginal candidiasis is the most common initial clinical manifestation of HIV infection in women (Carpenter et al 1991), and is a problem even at relatively well-maintained CD4 counts. Imam et al (1990) suggested a hierarchy of risk of candidal infection, with recurrent vaginal candidiasis becoming more common with early systemic immunosuppression, oral candidiasis becoming more common with moderate immunosuppression, and oesophageal candidiasis (an AIDS-defining diagnosis) typically occurring with severe immunosuppression. Not only are HIV-infected women more prone to recurrence, but yeasts other than *Candida albicans* (e.g. *Torulopsis glabrata*) are isolated more frequently and there is a shorter time before recurrence (Spinollo et al 1994). Response to treatment is usually good, but relapses frequently require retreatment or maintenance therapy.

Pelvic sepsis

Studies of HIV-infected women show no significant difference in the prevalence rates of gonorrhoea and Chlamydia

among HIV-positive and HIV-negative women (Minkoff et al 1999). Women with a concurrent sexually transmitted infection are more likely to have a higher viral load in vaginal secretions. Patients should be treated using standard therapy and referred to genitourinary medicine clinics for initiation of contact tracing and follow-up. Pelvic sepsis is probably more common in patients with HIV, but presentation can be varied with less severe symptoms and lesser rises in lymphocyte count, sometimes occurring at the lowest levels of immunocompetence (Korn et al 1993). In general terms, early treatment with standard antibiotics is appropriate and effective.

Syphilis

Syphilis should be treated similarly to HIV-negative patients, although some suggest a value in cerebrospinal fluid examinations before treatment or treatment that will cross the blood-brain barrier as HIV-positive patients may experience neurological manifestations earlier in the course of the disease.

Herpes simplex virus and genital ulceration

Frequency, duration and severity of herpes simplex virus attacks may be increased in HIV-positive women, particularly in immunocompromised women. Attacks may be avoided or treated with oral acyclovir, although resistance can occur, and culture and sensitivity testing is sometimes useful. In resistant cases of genital ulceration, directed biopsy may be necessary to exclude neoplasia.

Genital warts

Human papillomavirus (HPV), usually types 6–11, is common in HIV-infected women and may be more extensive and florid as compared to HIV-negative women. Treatment is along standard lines and, in those with severe immune compromise, resolution may be seen with increasing CD4 count resulting from systemic antiretroviral therapy.

Cervical intraepithelial neoplasia

CIN is common in women with HIV (Adachi et al 1993, Massad et al 1999), and prevalence increases with advancing immunosuppression (Schäfer et al 1991, Johnson et al 1992). HIV-positive women are more likely to be infected with HPV (Palefsky et al 1999), and more of this infection is the result of 'high-risk' HPV than in the HIV-negative population. Notably, HPV has been found in women who have sex exclusively with women; therefore, even this population must undergo cervical screening.

Data from the pre-HAART era suggested that CIN was more often of higher grade and more often aggressive in women with HIV compared with seronegative women, and that dysplasia was more likely to persist and progress than in seronegative women (Ahdieh et al 1999). Treatment with HAART may influence cervical dysplasia, although results are not consistent across studies, with some suggesting that women treated with HAART experience early regression of lesions (Heard et al 1998) and others showing no convincing evidence of an effect (Moore et al 2002).

There have been concerns about the usefulness of cervical cytology in HIV-infected women, and the optimal method and frequency of screening of this population remain unresolved. Larger studies have validated the use of cervical cytological screening combined with a low threshold for colposcopy and directed biopsy. The guidelines of the Royal College of Obstetricians and Gynaecologists advocate annual smears for women with HIV with no history of abnormality. Screening intensity should continue unaltered in women with excellent CD4 and viral load responses to HAART. High-grade cervical lesions should be treated appropriately, whilst women with low-grade abnormalities who are likely to adhere to follow-up may safely be monitored on a 6-monthly basis. The clinical usefulness and cost-effectiveness of HPV typing incorporated in routine clinical practice in women with HIV remains uncertain.

Cancer of the cervix

This diagnosis is a gender-specific AIDS diagnosis added to the AIDS definition in 1993. In the UK, there has not been a great rise in the number of cases of cervical carcinoma in HIV-positive women, and this may represent either effective screening or long latency of the disease, with more effective antiretroviral therapy likely to play a role. One study has shown that 2.5% of HIV-positive women aged 15–49 years in European countries have presented with this malignancy as a first AIDS-defining event (Serraino et al 2002).

Other genital neoplasias

Vulval and anal intraepithelial neoplasias have also been reported more commonly in HIV-infected women (Williams et al 1994), although the possible role of screening has not been evaluated.

Pregnancy

Fertility does not seem to be affected by HIV infection. Women (and men) with HIV are just as keen to pursue pregnancy as the HIV-negative population. Even before the advent of HAART, termination rates were no higher amongst those who were HIV-positive. Pregnancy does not appear to have a major effect on the rate of progression of HIV disease, and HIV infection itself (unless very advanced) does not affect pregnancy outcome. The main concern is the risk to the baby of becoming infected with HIV. Of infected babies, approximately one-third present early with symptoms and progress rapidly, one-third experience a relapsing–remitting course, and the remainder have more chronic infection and live well into their teenage years.

In order to prevent vertical transmission, the diagnosis of HIV must be made. The UK's record on antenatal diagnosis was extremely poor, and the majority of mothers of children vertically infected with HIV only discovered their own diagnosis when the child developed AIDS (Public Health Laboratory Service 1999). The Department of Health subsequently issued guidelines that all pregnant women should be offered an HIV test, with the aim that uptake of the test be 90% by the end of 2002 and the number of vertically HIV-infected babies reduced by 80% (Department of Health 1999). Great progress has already been made towards this

goal, with more than 90% of HIV-infected women diagnosed before giving birth in 2007. This high rate of detection in pregnancy means that the estimated proportion of exposed infants who become infected also remained low, at less than 5% (Health Protection Agency 2008).

Factors known to be associated with increasing risk of MTCT are increasing viral load, decreasing CD4 count, increasing duration of rupture of membranes, vaginal route of delivery, younger gestational age at delivery, the presence of other sexually transmitted infections, invasive medical procedures such as amniocentesis, fetal blood sampling, assisted delivery and breast feeding.

Care of a pregnant, HIV-positive woman has two main aims: first, to ensure the good health of the mother; and second, to attempt to reduce the risk of transmission of HIV to the baby to a minimum.

Antiretroviral therapy

If the mother is not yet on HAART but requires antiretroviral therapy, this should be given in accordance with the British HIV Association guidelines for non-pregnant women. Some women choose to defer treatment until after the period of organogenesis after discussion with their HIV physician. Women already taking HAART will often choose to continue their therapy, although uncertainty regarding the long-term effects of intrauterine exposure to antiretrovirals at any gestation may be a cause for anxiety.

In developed countries, most studies have shown a transmission rate of 15–25% in the absence of treatment, but the use of antiretroviral therapy in pregnancy has reduced transmission rates significantly. Use of AZT (a nucleoside) monotherapy was a breakthrough in reducing vertical transmission (Connor et al 1994). AZT commenced prior to the third trimester, given to the mother intravenously during delivery and given to the neonate orally led to a decrease in transmission by 67% in a placebo-controlled trial. AZT monotherapy does not reduce viral load to undetectable levels, and so does not prevent vertical transmission solely by an effect on viral load. Its precise mechanism of action remains uncertain. For this reason, although AZT monotherapy is still a regime recommended by the British HIV Association, there is a trend towards use of short-term antiretroviral therapy (START) regimes (combination therapy taken from approximately 28 weeks of gestation for the duration of the pregnancy), even in mothers who do not require antiretroviral therapy for themselves (i.e. who have a CD4 count >350). Unlike AZT monotherapy, START regimes aim to reduce viral load to undetectable levels to reduce levels of transmission as much as possible.

The potential for simplified regimes has been assessed, and nevirapine (an NNRTI) monotherapy given in two doses, one to the mother during labour and the other to the neonate at 48–72 h, has been shown to be more effective than a single dose of AZT in Africa (Guay et al 1999). However, evidence of subsequent nevirapine resistance (which will compromise effective treatment regimes available to the mother) continues to emerge and use of nevirapine monotherapy is generally not advised.

Obstetricians should be aware of possible side-effects occurring in women receiving antiretroviral therapy. Protease inhibitors may lead to glucose intolerance and an increasing likelihood of gestational diabetes, whilst two of

the nucleoside agents (DDI and D4t) have been associated with the development of lactic acidosis (three fatal cases), which may mimic the haemolysis–elevated liver enzymes–low platelets syndrome. These agents should probably be avoided if possible. Those women with greater immune compromise may be taking antibiotic prophylaxis against opportunistic infection. Septrin, the agent most commonly used, is a folate antagonist, and prescription of folate supplements should prevent developmental abnormalities.

All women should be registered prospectively on the Anti-retroviral Pregnancy Registry (managed by Glaxo-SmithKline), set up to monitor short- and long-term side-effects. Women and their children should also be registered with the Royal College of Obstetricians and Gynaecologists and the British Paediatric Surveillance Unit. Efavirenz (an NNRTI also known as DMP) has been shown to cause a range of defects of varying severity in cynomolgus monkeys, and its use should be avoided if at all possible. In counselling women in this area, it is important to weigh up the uncertainty regarding toxicity against the undisputed benefits of preventing vertical transmission.

Delivery route

In the majority of cases, transmission occurs at the time of delivery; however, this will occur *in utero* in a small percentage of cases. There is now conclusive evidence to recommend prelabour lower segment caesarean section. A meta-analysis of 15 prospective cohort studies showed a 50% reduction in transmission (International Perinatal HIV Group 1999), and a 70% reduction was found in the European controlled trial (European Mode of Delivery Collaboration 1999). There is uncertainty regarding whether there is a persistent benefit in caesarean section when the mother has an undetectable viral load (<50 copies/ml).

Breast feeding further increases the risk of transmission of HIV by between 7% and 22% (Dunn et al 1992). In the developed world, the majority of postpartum transmission is the result of breast feeding, and its avoidance significantly reduces rates of infection (Kreiss 1997). If a woman decides to breast feed despite this evidence, she should be advised to breast feed exclusively as transmission rates are highest when mixed feeding is employed. There may well be considerable cultural difficulties around not breast feeding, and women need support and advice regarding how to deal with this.

Transmission rates

Transmission rates of between 1% and 2% can be achieved by a combination of antenatal treatment with antiretrovirals, AZT infusion at a prelabour caesarean section, avoidance of breast feeding and infant antiretroviral therapy. Treatment and follow-up of the infant should be undertaken by a specialist paediatric team.

Pregnancy Control

Contraception

All patients should be advised to use barrier contraception to protect against transmission of HIV, transmission of

resistant HIV, other infections and pregnancy. Many women decide to use a 'belt and braces' approach, using an additional method to reduce the risk of unplanned pregnancy further, although there is some evidence that condom use declines in HIV-positive women who use combined oral contraception (COC). Women taking antiretroviral therapy which may induce or suppress liver enzymes to varying degrees should be made aware of the possible risk of sub-therapeutic levels of their COC pill, and advice to use condoms as well should be reinforced. Those using depot injections and taking HAART should have injections every 10 weeks. HAART regimes containing protease inhibitors have been associated with elevations in blood triglycerides and cholesterol, which should be monitored closely in those taking COC.

Previous advice was for women with HIV to avoid use of intrauterine devices because of potential risks of infection and a possible increase in risk of transmission to male partners resulting from increased duration and heaviness of menses. This has not been substantiated (European Study Group on Heterosexual Transmission of HIV 1992), and this may well be a method of choice in carefully selected candidates (Sinei et al 1998). The progestogen intrauterine system is increasingly used for women with HIV, with the benefits of excellent contraception and a reduction in blood flow.

Sterilization should be undertaken following the same guidelines as apply to other women. However, care needs to be taken around the time of diagnosis of HIV, when women have not had sufficient opportunity to adjust to the diagnosis and may subsequently regret the procedure.

Spermicides, such as nonoxynol-9, appear to inactivate HIV *in vitro* but may not be so effective *in vivo*. Unfortunately, there is evidence that nonoxynol-9 may cause mucosal inflammation that might lead to an increased risk of HIV transmission. The contraceptive implant Implanon has not been evaluated in these women, although it is likely to play a role. All women should be aware of emergency contraception (Levonelle and emergency intrauterine device insertion) and where this can be accessed.

Termination of pregnancy

Women requesting termination of pregnancy should be referred to an appropriate clinic where both medical and surgical options may be offered as appropriate. As for HIV-negative women who have had unprotected sexual intercourse, sexually transmitted infection screening may also be appropriate at this time.

Planning pregnancy

Any woman planning pregnancy should be advised to stop smoking and reduce alcohol consumption, and folate supplements should be prescribed. It is sensible to assess the woman's overall state of health, and in the HIV-positive woman, this will include checking recent levels of viral load and CD4 count. HAART regimes containing a known teratogen such as efavirenz should be altered if possible.

Both partners may be HIV infected or only one. Where only the woman is infected, the entirely safe method of

artificial insemination using the partner's semen can be employed. Advice should be given regarding the timing of ovulation and the optimum time of insemination, with some women preferring to buy commercially available ovulation predictor kits.

An HIV-negative woman may have an HIV-positive male partner. HIV does not appear to infect sperm directly. Therefore, if sperm can be isolated from the white blood cells and the seminal plasma in a 'sperm-washing' procedure, it should be possible to inseminate a woman safely. Semprini et al (1992), Gilling-Smith (2000) and Marina et al (1998) have experience of more than 3000 cycles of sperm washing and intrauterine insemination or in-vitro fertilization (resulting in 300 live births) with no reported seroconversions. The sperm-washing procedure is expensive and not currently freely available, and some couples may decide to pursue 'unsafe' insemination with unprocessed semen or to practice 'unsafe' sex. Mandelbrot et al (1997), however, have published results of a study of 92 HIV-negative women whose partners were HIV positive and who had 104 pregnancies. All couples had unprotected intercourse during the fertile period as determined with commercial ovulation predictor kits. There were only four seroconversions, all in couples who did not use condoms consistently during the rest of the cycles.

Even when both partners are infected with HIV, condom-free intercourse cannot be recommended because of the possibility of transmission of resistant virus. Couples may choose to perform, possibly less risky, home insemination.

Infertility

This has been a contentious but important area. Women and their partners should not automatically be denied access to treatment because of HIV infection. As with HIV-negative women with potentially life-shortening conditions such as complicated diabetes, post transplant or a history of cancer, HIV-infected women must be equipped with information and allowed to make their own reproductive decisions (Gilling-Smith et al 2001).

Continuing childlessness can be extremely distressing, and factors such as current state of health and long-term prognosis, support networks and motivation to pursue often stressful investigations and treatments should be discussed and counselling given. Advice regarding HIV, treatment and prevention of vertical transmission should be accurate, up to date and given in conjunction with expert HIV physicians.

Infertility may present in a number of different situations with one or both partners being infected with HIV. Where in-vitro fertilization is necessary, the possible emotional and financial costs should be discussed, and this treatment should only be carried out where there are provisions to perform treatment safely and without risk of infection to others.

Preparation for Gynaecological Surgery

Most HIV-infected women will tolerate surgery well, even if their CD4 count is low. Chest and wound infections are more common, but with the use of prophylactic antibiotics

and physiotherapy, these will not usually present serious problems. Where surgery is indicated, HIV status itself should not affect the decision to operate.

Nosocomial Transmission

Occupational transmission to healthcare workers

Most occupational transmission has occurred following needlestick or other sharps injuries, and there have been a very few documented seroconversions after contamination of broken skin or mucous membranes. The risk of acquiring HIV from a single accidental parenteral exposure to infected blood has been estimated at approximately 0.3%. Those performing surgical procedures should employ universal precautions, bearing in mind the prevalence of undiagnosed HIV and hepatitis B and C infection. The last two conditions are much more readily transmitted than HIV. A woman with HIV should not be subjected to any unnecessary and discriminatory infection control procedures which could isolate her or draw attention to her before other patients or relatives.

Postexposure prophylaxis

Immediately after a percutaneous or mucous membrane exposure to potentially HIV-infected blood, thorough washing with warm running water and soap and clinical evaluation of the injury should be performed. Any bleeding should be encouraged. Consultation with local HIV experts should be as rapid as possible in order that appropriate prophylactic antiretroviral therapy can be commenced, preferably within 1 h, to reduce the risk of seroconversion (Department of Health 2000).

HIV-infected healthcare workers

The Department of Health (2000), Medical Defence Union and UKCC [United Kingdom Central Council for Nursing, Midwifery and Health Visiting (now Nursing and Midwifery Council, NMC)] are clear that HIV-positive health workers should not take part in invasive 'exposure-prone' procedures, and the individual should inform their occupational health department of their status. In addition, the General Medical Council recommends that staff who think they have been at risk should be tested confidentially.

Conclusion

The national strategy for sexual health and HIV (Department of Health 2001) aims to reduce the transmission of HIV, increase the diagnosis of prevalent cases, improve the health and social care of people with HIV, and reduce the stigma attached to the diagnosis. Rates of HIV infection continue to increase, and the number of woman affected is rising. Use of HAART has dramatically improved the prognosis for patients with HIV. Obstetricians and gynaecologists should be aware of the possibility of HIV infection in their patients, and should facilitate HIV testing in order that women are able to experience the benefits of therapy.

KEY POINTS

1. There is a steady increase in the prevalence of HIV infection in women.
2. Whilst HIV remains an incurable condition, advances in therapy have improved the prognosis dramatically.
3. Women with HIV experience the same range of gynaecological problems as their HIV-negative counterparts, and their HIV status itself should not influence the treatment they receive.
4. CIN is more common in this population and women should have an annual screen.
5. MTCT can be reduced to under 2% with appropriate intervention.
6. HIV infection should not influence the availability of fertility investigation and treatment.
7. Obstetricians and gynaecologists should be aware of the possibility of HIV in their patients, and should facilitate testing to monitor infection rates and to alert infected women to their need for treatment.

Introduction

There seems to be an escalating epidemic of rape globally, and it is known that the majority of sexual assaults are not reported to the police, and domestic or spousal rape is even less commonly reported. Sexual assault is not only a serious criminal justice problem but is also a major public health issue. In the UK, 'intimate violence' is a collective term used for partner abuse, family abuse and sexual assault, with 'sexual assault' being defined as indecent exposure, sexual threats and unwanted touching ('less serious'), rape or assault by penetration including attempts ('serious') by any person including a partner or family member (Roe 2008). Annual figures relating to crime in England and Wales are published as the Home Office Statistical Bulletin, reflecting not only the police recorded crime but also findings from the British Crime Survey (BCS) (Kershaw et al 2008). The BCS is a large victimization survey of approximately 47,000 adults living in private houses in England and Wales. Based on the 2006/07 BCS self-completion module on intimate violence, approximately 3% of women and 1% of men had experienced a sexual assault (including attempts) in the previous 12 months. The majority of these were less serious sexual assaults. A significant minority (40%) of victims of serious sexual assault had not told anyone about their most recent experience, with only 11% informing the police. A further worrying statistic is that for victims of serious sexual assault, 37% were repeat victims. In a three-city comparative study of client violence against prostitutes working from street and off-street locations, 28% of women involved in street-based prostitution reported attempted rape (Barnard et al 2002).

In a global context, it is known that conclusions drawn from crime statistics are virtually useless for estimating the

incidence of sexual assault because women are universally reluctant to report rape to the authorities. In 2007, the Home Office in the UK produced the first cross-government action plan on sexual assault, which included a range of measures aimed at improving the criminal justice response to sexual violence.

Most rape allegations do not proceed to court; in 1982–1985, 20% of reported cases went to court in Oslo (Bang 1993). In the UK, the conviction rate for all reported cases is currently between 5.7% and 6.5% (Dyer 2008, Williams 2009). The Home Office figures suggest that actual numbers of convictions for rape are increasing year on year, but the increase in convictions is not keeping pace with the increased reporting, thus there is a high level of attrition or case drop-out. Victims who decline to complete the initial investigative process are more likely to do this in areas where there is no sexual assault referral centre (SARC) (Kelly et al 2005). SARCs are widely regarded as the ideal environment for quality forensic examination, ensuring that the victim has access to other services such as sexual health and professional counsellors.

Legal aspects

Under the UK Sexual Offences Act (SOA) 2003, a person can legally consent to sexual activity if he or she is aged 16 years or older. The SOA 2003 covers over 50 sexual offences, and sexual assault is defined as a non-consensual sexual offence, with consent being defined as having the freedom and capacity to choose.

The SOA 2003 was a significant overhaul of the UK law that dealt with sexual violence, and there are now new offences such as the offence of rape to include oral and anal penetration with a penis, and assault by penetration;

penetration may be by part of the defendant's body but not the penis, or penetration with an object (Rights of Women 2008).

Medical practitioners need to be aware of the legal context in which they gather evidence, and the forensic examination has a dual purpose: firstly, to address the immediate needs and concerns of women; and secondly, the justice system's need for the documentation of physical findings, the rigorous collection and preservation of evidence, an interpretation of the findings, and provision of expert opinion in legal proceedings (Kelly and Regan 2003).

Her Majesty's Government have indicated that they have strengthened the capacity of specialist rape prosecutors and rape coordinators to ensure that the best case is built, and expanded special measures to make it easier for vulnerable victims to give evidence (H.M. Government 2007). Indeed, the Youth Justice and Criminal Evidence Act 1999 legislation gives vulnerable and intimidated witnesses the opportunity to give evidence from behind screens, by video link or for the court to be cleared.

Reasons for failure to report sexual assault

The most important barriers to reporting rape and sexual assault are:

- ignorance about where to find help;
- fear of not being believed;
- fear of becoming involved in complicated police investigations and subsequent court proceedings;
- known low conviction rates;
- concerns about confidentiality;
- anxiety, guilt, shame, embarrassment and not wanting friends and family to know;
- fear of reprisal or retaliation by perpetrator; and
- cases involving a known perpetrator (Kelly et al 2005).

Attrition

Attrition in sexual offences cases refers to cases dropping out from the time of initial complaint to the trial. There is an increasing justice gap for victims as the increasing number of convictions for rape is not keeping pace with the increased reporting (H.M. Crown Prosecution Service Inspectorate 2007). Attrition during investigations begins early. Two significant factors were identified by the review of the handling of investigations by the police and Crown Prosecution Service Inspectorate, one of which is the decision by the victim not to complete the initial process. The other factor was the decision to withdraw support for the investigation or prosecution (H.M. Crown Prosecution Service Inspectorate 2007).

In 2005, Kelly et al pointed out that the majority of sexual assault incidents are reported to the police within 24 h, but that over half of cases lost at the investigative stage are due to evidential issues such as:

- complainant with learning difficulties or mental health problems, or victims who are otherwise unable to give a clear account;
- DNA testing not conducted; and
- an offender was identified but not traced.

Victim withdrawals occur primarily:

- when the victim declines to complete the initial investigative process;
- at the police stage, where over one-third of cases are lost; and
- where there is no SARC (Kelly et al 2005).

Sexual Assault Referral Centres

In early 2009, there were 24 SARCs in England and Wales, the main client group being complainants of recent sexual assault and where the victim has access to a range of agencies including health, the services of counsellors and trained volunteers (H.M. Crown Prosecution Service Inspectorate 2007). The UK Home Office has indicated that SARCs should have the infrastructure to support ongoing victim care, and there should be adequate training and development and quality assurance. There should also be evidence of operational and management policies and procedures (Home Office 2005). It is important that despite the need for cleanliness in the examination room, there are separate interview rooms with a calming and relaxing feel about them (Kelly and Regan 2003).

The services that SARCs provide include:

- experienced women doctors to conduct the medical examination in a purpose-built suite (Figure 65.1);
- confidential access to experienced counsellors regardless of whether the woman reports the assault to the police or not;
- for those women who wish to involve the police, specially trained women police officers to conduct the interview and take a statement; and
- referral may be through the police, general practitioner, hospital doctor or by self-referral without any involvement from the police.

Figure 65.1 Examination suite.

Figure 65.2 Evidence kit.

The clinical requirements of the SARC include:

- clinical and evidential protocols;
- evidence kits (Figure 65.2) which are applied flexibly to fit the nature of the case;
- examination suite with appropriate cleansing and decontamination services;
- first aid facilities;
- emergency contraception supplies and literature;
- access to services for the prevention and management of sexually transmitted infections (STIs); and
- access to psychosocial support.

Consenting to a medical and forensic examination

In achieving consent for a forensic examination, it is important to remember the principles of confidentiality. The General Medical Council (GMC) indicate that 'Patients have a right to expect that information about them will be held in confidence by their doctors', accepting that doctors may have contractual obligations to third parties, such as in their work as police surgeons, and in such circumstances, disclosure may be expected (General Medical Council 2006). In such circumstances, the GMC recommends that the doctor is 'satisfied that the patient has been told at the earliest opportunity about the purpose of the examination and/or disclosure, the extent of the information to be disclosed and the fact that relevant information cannot be concealed or withheld'.

Consent to forensic medical examination should include the nature of the medical examination, the collection of forensic evidence, that photography may form part of the record of the examination and report, and those details in the medical record may be disclosed to police and the Crown Prosecution Service (CPS) for use in evidence.

The woman should also be made aware that the examination can be discontinued at any stage if she so wishes. The stage of the examination reached and the time at which she decides against further examination should be recorded.

The complainant may agree to a 'qualified consent' (i.e. to the release of information to the prosecution without allowing scrutiny by the defence). If she does not consent to

release of the medical details, the examiner may be ordered to disclose information by a judge, in which case the forensic physician (FP) should only disclose information relevant to the request for disclosure. In the 'Disclosures to courts or in connection with litigation' section of the GMC document 'Confidentiality: Protecting and Providing Information', it is stated 'You should object to the judge or the presiding officer if attempts are made to compel you to disclose what appear to you to be irrelevant matters' (General Medical Council 2004). The section continues, 'You must not disclose personal information to a third party such as a solicitor, police officer or officer of a court without the patient's express consent'.

If the woman is a non-police referral, she should be informed that she could pursue a formal complaint subsequently, at which stage additional consent should be sought.

Examination of the complainant of sexual assault

Forensic examination is only the first part of the immediate health-based response, the key elements of which include:

- treatment and documentation of injuries;
- collection of medicolegal evidence and maintaining the chain of evidence;
- treatment and evaluation of STIs;
- pregnancy risk evaluation and prevention; and
- crisis intervention and arrangements for counselling.

Forensic examination can provide relevant evidence up to 72 h after an assault, but can even be useful after that time (e.g. if a woman is bleeding or in pain, or if she has been subjected to a serious level of physical violence).

The forensic examination may provide vital evidence that identifies the assailant and/or supports the complainant's account should the case come to court. Not only does the forensic examination itself increase the likelihood of legal action, but having a forensic examination doubles the likelihood of prosecution (McGregor et al 2002, Kelly and Regan 2003).

Who should undertake the examination?

In ideal circumstances, the victim of sexual assault should be allowed to choose the gender of the examining doctor. In the 1980s, the gender of the examining physician was not always felt to be a factor affecting the victim's response to the medical examination (Hockbaum 1987), but recent evidence shows that most victims (male and female) prefer female staff; 43.5% of victims said that they would not continue the forensic examination if the doctor was male (Chowdhury-Hawkins et al 2008).

Training in sexual assault examination

Few doctors have received formal training in the principles of clinical forensic medicine.

To ensure optimal care for the victims of sexual assault, a coordinated multidisciplinary approach should be made to tackle the theoretical and practical training issues. Local and national programmes have been developed at all levels, from specialist registrars through to continuing medical education

of those actively involved in rape examination. Subspecialist gynaecology trainees in sexual and reproductive health are expected to complete the forensic and domestic violence competencies module as part of their subspecialty training, which emphasizes the importance of preserving evidence and maintaining the evidence chain whilst providing appropriate sexual and reproductive health care for the complainants of sexual assault (Royal College of Obstetricians and Gynaecologists 2009).

Sexual assault victims may present to an accident and emergency (A&E) department and be seen by the on-call doctor, and whilst resuscitation and immediate clinical management are their prime concern, every A&E department should have a policy for the management of such women and training for first-line staff in the initial care of such vulnerable victims.

One area of training that is especially valuable is court witness skills, and it is vitally important to maintain one's skills in this field through continuing professional development programmes in forensic gynaecology.

Role of the police officer

The police officer has an important role in the rape victim's experience and decision to further pursue legal prosecution. Specially trained police officers not only gather evidence but also have a unique role in liaising with victims of sexual assault, offering advice and information about the criminal justice process as well as taking the formal, detailed statement. In addition, the officer accompanies the complainant to the examination centre, ensuring that she takes a change of clothes with her. The police officer is responsible for the 'Early Evidence Kit' collection of first (timed) urine sample for urine toxicology; it is particularly valuable where there is likely to be a delay before the medical examination. Where an oral sex allegation has been made, the police officer will ask the woman to use a mouth rinse as this is known to be more efficient at recovering semen from the oral cavity. Other early evidence samples include used sanitary wear and toothbrush where oral sex is being alleged and the complainant has cleaned her teeth.

Prior to the doctor taking a history of the assault, the officer provides a summary of the allegation for the doctor. During the examination, the officer may act as a chaperone for the examining doctor and assist in a discreet manner, ensuring that each forensic sample is correctly labelled and sealed. The forensic samples are then sent to a central submissions unit for later dispatch to the forensic science laboratory.

The examining doctor

The experienced clinician will realize that pre-existing diseases, mental health issues and previous trauma can affect the interpretation of the forensic examination findings. It is important to take an accurate account of the event to ensure that an appropriate examination is undertaken and that the collection of forensic evidence is complete. The use of a record of examination with checklists and body diagrams to illustrate the findings provides invaluable assistance to the examining doctor, who is not infrequently called to a complainant in the middle of the night.

The examining doctor must be objective and non-judgemental, and must avoid giving even the smallest cues of suspicion or disbelief which may heighten the victim's anxiety and emotional trauma, and cause a spiralling decline as her guilt and shame increase and her story is shaken (Dupré et al 1993).

Forensic examination is time-consuming and often lasts in excess of 2 h. A speedy response from the forensic examiner is, however, essential for evidential purposes and victim comfort. The importance of examination within 24 h was emphasized in a study on the outcome of sexual assault victims who pursue legal action (Wiley et al 2003). The characteristics positively associated with a legal outcome included:

- being examined within 24 h of assault;
- partner/spouse as an assailant;
- oral assault; and
- anogenital injury (AGI).

Cross-contamination is a major concern now that DNA can be detected in smaller and smaller quantities, and SARCs should have policies in place for cleansing of the medical suite as contaminated samples could have a significant impact on the investigation of the offence and might even result in the investigation being abandoned. FPs should have their DNA added to the police staff elimination database so that checks can be made if a cross-contamination issue arises.

The Record of Forensic Examination

Documentation

The record of the forensic examination should be seen as a confidential *aide memoire* for the clinician, and should contain the following sections.

Complainant and SARC personnel information

Consent

Details of consent to forensic medical examination include:

- medical examination: non-genital/genital;
- recording of the details of the examination;
- retention of relevant items of clothing for forensic examination;
- collection of forensic evidence;
- disclosure of details of the medical record and/or laboratory tests to police/Crown Court/CPS for use in evidence; and
- the taking of photographs which will be used as part of the medical record, may form part of the report based on the examination and may be revealed in subsequent court proceedings.

Medical details

It is the clinician's responsibility to obtain a pertinent medical history, remembering that pre-existing conditions may affect interpretation, such as scars from surgery.

The clinician should enquire about general health and current medical problems, current or recent genital symptoms, bladder or bowel symptoms, and relevant past medical

history. Relevant obstetric details should include her parity and mode of delivery. Medication details should be sought, including prescribed and over-the-counter drugs, together with details of street drugs if this is thought to be relevant, as well as social and employment information.

It is essential to gather information about the last menstrual period, time interval since the last sexual intercourse if this is within 14 days, condom usage and any other contraception.

Account of the event

This is usually in the form of an account of events from the complainant and the police officer taking details of the sequence of events before, during and after the incident. Such an account allows the doctor to adapt the standard forensic examination according to the circumstances of the assault. The complainant may, however, be unable to recall the details of the assault, possibly due to the influence of alcohol/drugs at the time of the assault or subsequently. The victim may be naturally reticent, as in the elderly victim, or already suffering 'memory block' associated with rape-related post-traumatic stress disorder (PTSD). Hence it is safer practice to complete the full forensic sampling at this time, usually the only opportunity afforded to the doctor to collect evidence. Loss of evidence may be caused by a delay in presentation, so particular attention should be paid to the time interval since the incident.

Details of the complainant's actions taken since the incident should be recorded, such as specific details of genital cleansing and change of sanitary protection.

General medical examination

The details of the complainant's general appearance should be documented (e.g. build/body mass index, hygiene, demeanor, mood and details of any disability). In addition, it is important to comment upon her reaction to the examination. A sexual examination kit with all necessary equipment should be to hand. For complex injuries, it is very important to request the assistance of a female police photographer.

There are a number of key sites where injuries are most likely to be found during the examination of the victim of sexual assault (e.g. thighs, neck, inner aspect of upper arms and face). It is important that the medical record should contain a reference to any area that is omitted. All injuries should be drawn on body diagrams with corresponding measurements and description, each injury being numbered so that it can be cross-referenced in the statement. Each body diagram used should include a statement to say that the injuries are not drawn to scale.

The Faculty of Forensic and Legal Medicine (FFLM) has reminded forensic examiners about the importance of recording and measuring injuries caused by teeth, and that a full description and overall dimensions should be documented (Rowlinson et al 2008).

The severely injured patient

The medical needs of the victim must take priority over the need to achieve forensic samples, and urgent medical advice should be sought, where necessary, in an appropriately equipped setting (e.g. an A&E department). The reason for delay in undertaking the forensic examination should be

carefully documented in the medical record. The sexual examination kit can be collected from the SARC for use in a hospital ward or outreach facility once the complainant's condition is deemed stable and she is willing and able to consent to forensic examination.

Genital examination

The genital examination should begin with a description of the external genital appearance and the presence of any anatomical variation or disease process. There should be a careful documentation of any injuries, using a standardized labelled diagram to record such findings. It can be helpful to use the analogy of a clock face to describe the site of an injury where the 12 o'clock position is anterior. The details of the internal examination (speculum and digital) should be documented next, describing the site and nature of any injuries, with an estimate of the dimensions and the nature of any discharge, blood or fluids seen.

Colposcopic examination

Colposcopic examination is known to increase the positive genital findings compared with inspection of the genitalia. A study of 200 cases of sexual assault examined with a colposcope revealed positive findings in 32% on inspection; however, the positive findings increased to 87% with colposcopic examination (Sommers 2006). Where forced digital penetration is alleged, colposcopy has been found to be particularly useful (Rossman et al 2004).

Questions have been raised regarding why photocolposcopic examination of AGI in a sexually assaulted child is considered the 'gold standard' of examination, yet gross visualization is the standard procedure in adult examination (Brennan 2006). A possible explanation is that colposcopy is seen as an invasive procedure which is ethically unacceptable.

The significance of some of the genital findings during the colposcopic examination remains controversial, especially when images are interpreted by inexperienced clinicians (Templeton and Williams 2006).

If the examiner is unable to carry out the internal examination, the reason should be documented, especially if this is due to client distress or consent being withdrawn. Where indicated, a meticulous description of the perianal and anal examination, and proctoscopy findings should be documented.

Forensic sampling

The forensic evidence collected during the examination is used to help to:

- confirm that sexual contact has taken place;
- establish the lack of consent on the part of the victim;
- establish the identity of the assailant;
- estimate the force used; and
- corroborate the complainant's account.

The FFLM has produced a guideline for good practice regarding collection of forensic specimens which is updated at 6-monthly intervals (Faculty of Forensic and Legal Medicine 2008a). Most SARCs/police forces will have access to a 'sample reference form' (Figure 65.3), with tables listing the forensic samples with their corresponding exhibit number, sample description etc. Recent evidence has shown that posi-

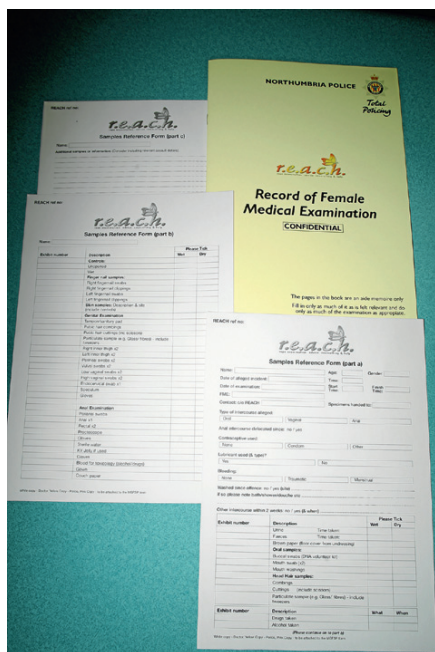

Figure 65.3 Sample reference forms.

tive forensic results are achieved in approximately 38% of forensic examinations (McGregor et al 2002).

Postexamination arrangements

Communication with the forensic science laboratory

The forensic examiner should complete a forensic specimen form and assist colleagues in the laboratory by providing a brief description of the facts of the case.

Photographs of injuries

Where there is complex skin trauma, photography may act as an adjunct to the description to the findings. It has been claimed that a carefully observed, well-documented description of any injury or group of injuries is worth many photographs (Bunting 1996). Others claim that a photograph can be worth a thousand words if the assailant is claiming consent and the attorney has pictures of the victim with a black eye or worse (Ledray 1993).

Re-examination

This is occasionally indicated if:

- genital injuries are not visible but were anticipated from the account of the incident;
- the examination took place shortly after the incident; or
- there is tenderness on examination.

Referral to counselling services

At best, a follow-up rate of 31% was achieved in a sexual assault follow-up evaluation clinic, despite efforts to encourage female victims to use the clinic (Holmes et al 1996) (Figure 65.4). Our ability to reduce the occurrence of the long-term effects of sexual assault is limited by the low rates of reporting and lack of focused follow-up for those who do report their assault. However, the doctor can significantly

Figure 65.4 Counselling room.

enhance the uptake of counselling in the aftermath of an assault.

Emergency contraception

Hormonal pregnancy prevention is prescribed as soon as possible and up to 72 h after the incident (levonorgestrel 1.5 mg as a single dose), and an intrauterine contraceptive device with antibiotic cover can be inserted at any time up to 5 days after the incident.

Sexually transmitted infections

The frequency of STIs in victims of sexual assault is difficult to estimate due to the low reporting and follow-up of victims. In Mexico, the frequency of STIs was 20% amongst 213 patients (Martinez et al 1999).

Clients are offered referral to a genitourinary medicine (GUM) clinic, where they are seen for screening for STIs 10–14 days after the assault to allow for incubation of newly acquired infection (Home Office 2005). If, however, there are no SARC facilities for human immunodeficiency virus (HIV) and hepatitis screening, the client should be seen in the GUM clinic as soon as possible, preferably within 72 h. Where the complainant declines referral, the forensic examiner should recommend antibiotic prophylaxis against gonorrhoea and chlamydia.

HIV testing and hepatitis screening

The risk of acquiring HIV and hepatitis B following rape in the UK is rare and is estimated to be approximately 0.1–0.2% for vaginal rapes and 1–2% for anal rapes for HIV in developed countries (Kelly and Regan 2003). HIV risk assessment should be carried out, assessing the type of assault and enquiring about additional factors which increase or decrease risk (trauma, breach of hymen, condom usage), together with an appraisal of known or overt risk factors to do with the assailant (Home Office 2005).

Postexposure prophylaxis, if given, should be started as soon as possible after sexual assault as it is unlikely to be beneficial after 72 h. The Clinical Effectiveness Group of the British Association for Sexual Health and HIV have updated the UK guideline for the use of postexposure prophylaxis for

HIV after sexual exposure (PEPSE), facilitating calculation of the risk of HIV infection after potential exposure, recommending when PEPSE would and would not be considered. It is believed that transmission of HIV is likely to be increased following aggravated sexual intercourse (anal or vaginal) such as occurs during sexual assault, and the authors recommend that clinicians should consider recommending PEPSE more readily in such situations where the 'source' individual's HIV status is unknown (Fisher et al 2006).

Risk assessment for hepatitis B infection in sexual assault victims should be along the lines of the HIV assessment. Hepatitis B vaccination is recommended for all victims of sexual assault, and hepatitis B immunization should be considered for a non-immune contact after single unprotected forced sexual exposure if the assailant is known or is strongly suspected to be infectious as long as it is given within 7 days; it is, however, best given within 48 h of the contact.

Odontological examination

The FFLM recommend an odontologist for photography of injuries caused by teeth. Some injuries may become clearer with time, so repeat photography should be considered (Rowlinson et al 2008).

GP letter

A letter to the general practitioner should be supplied, with victim's consent, and take-home literature about local support networks given.

Injuries

Non-genital injury

The majority of female victims (40–88%) will have some form of physical injury, although most will be of a minor nature (Bowyer and Dalton 1997, McGregor et al 2002, Palmer et al 2004). Less than 5% of complainants attending SARCs require hospital admission for treatment (Home Office 2005). Where a clinical injury extent score was applied to rate the physical severity of the assault in 113 cases of sexual crime, the injuries were ranked as:

- 44% with light injury;
- 18% with moderate injury; and
- one victim with severe injury (Alempijevic et al 2007) (1%).

Also, 63.4% of victims had one or more injuries, whereas 35.6% had no injuries. Injuries, predominantly bruises, were located on limbs (32%), face (23%) and torso (7%).

Genital injury

The overall incidence of genital injury is of the order of 20–49% (McGregor et al 2002, Palmer et al 2004, Drocton et al 2008). Genital injury in the absence of non-genital injury is rare (3%) (Palmer et al 2004). Palmer et al also found that risk factors for genital injury were:

- the presence of non-genital injury [odds ratio (OR) 19, 95% confidence interval (CI) 6.0–63.0];
- threats of violence (OR 3.7, 95% CI 1.5–8.9); and
- being aged over 40 years (OR 5.6, 95% CI 1.6–20.3).

Clinical injury extent scoring

McGregor et al devised a clinical injury extent scoring, categorizing injuries as none, mild, moderate or severe, based upon observed genital and extragenital injury (McGregor et al 1999). Criteria for clinical injury scoring were devised; for example, one of the criteria for a moderate injury score was 'injury or injuries expected to have some impact on function'. The results supported the hypothesis that there is an association between the laying of charges and the presence of documented moderate or severe injury. These findings were supported by a subsequent study where a gradient association was found for genital injury extent score and charge filing, but an injury extent score defined as severe was the only variable significantly associated with conviction.

Genital trauma associated with forced digital penetration has been found in 81% of complainants (Rossman et al 2004). This retrospective study documented the frequency and type of injury in 53 women in whom forced digital penetration was the only reported type of assault. The mean number of genital injuries was 2.4, and 56% of the injuries occurred at four sites: the fossa navicularis, labia minora, cervix and posterior fourchette. The most common types of injury were erythema (34%), superficial tears (29%) and abrasions (21%).

Forensic examiners remain unsure about why some sexual victims display acute injury while others do not (Drocton et al 2008). The potential reasons for these differential findings among female victims were explored for 3356 complainants, of whom 49% displayed AGI. Significant increased risk for AGI was noted with vaginal penetration or attempted penetration using penis, finger or object, and anal-penile penetration. Victims less likely to display AGI were those with a longer postcoital interval and those with increased parity.

The Influence of Alcohol- and Drug-Facilitated Sexual Assault

The true extent of alcohol- and drug-facilitated sexual assault (DFSA) is not known and is difficult to estimate, but drugs and alcohol do impair the recollection of events surrounding the sexual assault, making identification and prosecution of the assailant even more difficult. The SOA 2003 states that voluntary intoxication affects a woman's capacity to choose. The BCS also noted that a significant minority of victims report that they were under the influence of drink in the most recent incident of sexual assault they had experienced (Kershaw et al 2008). Alcohol is also known to be a factor involved in 34% of rape cases reported to the police (Kelly et al 2005). The proportion of DFSA in four American localities was estimated with urine and hair specimens tested for 45 drugs (Juhascik et al 2007). Of 144 subjects, 43% were characterized as DFSA. There was considerable under-reporting of the use of drugs by the subjects.

A study into the nature of DFSA in England examined samples from 120 cases of sexual assault (Operation Matisse 2006). One hundred and nineteen of the 120 victims reported drinking alcohol; however, alcohol was only detected in 62 (52%) cases. In 22 of the 62 (35%) cases, blood alcohol at the time of the incident was estimated to

be greater than or equivalent to 200 mg% (i.e. more than twice the driving limit of 80 mg%). The authors commented that a combination of drugs and alcohol exacerbates intoxication, and suggested that some of the cases could be opportunistic DFSA (i.e. where an assailant assaults a victim who is profoundly intoxicated by her own action), whereas other offenders facilitate sexual assault by administering drugs, including alcohol, to the victim.

Description of Wounds

The doctor examining a complainant of sexual assault may experience difficulty with the nomenclature when describing wounds, and may be daunted by the medicolegal significance of the lesions. Even more difficulty may be encountered when asked to give an opinion as to how they may have been caused. The following classification has been adapted from Crane (1996).

Bruises

A bruise is caused by the application of blunt force to the skin that damages small blood vessels beneath the skin surface. The blood then spreads through the tissue spaces. Bruises resolve over a variable period of time. On the whole, blue and black bruises are indicative of recent trauma, but estimating the age of a bruise is a risky undertaking and should be avoided at all costs, especially if one is asked to do so in court.

Petechiae

Petechiae are pinhead-sized haemorrhages within the skin caused by:

- mechanical trauma, with underlying clothing leaving an imprint of the material's texture as petechiae;
- sucking, as in 'love-bites'; and
- congestion/mechanical asphyxiation on face, upper neck, conjunctiva as in childbirth and strangulation.

Purpura

Purpura are larger haemorrhages within the skin, often seen in the elderly.

Haematoma

Haematomas are blood that collects as a mass beneath the skin.

Factors to remember about bruising

- May be delayed in appearance. Deep bruises can take 12–24 h to appear.
- May not reflect the size of the object impacting with the skin.
- May not represent the point of impact due to tracking along tissue planes.
- May not represent the severity of the blow due to age or frailty of tissues.
- Can vary according to the site (e.g. underlying bone).
- Appearance of a bruise can be affected by skin colour.

- Interpretation of bruises in hairy areas can be difficult.
- Can assist in interpretation of causation (e.g. finger-tip bruising on inner aspect of upper arms).
- There are considerable difficulties in timing injuries by the colour of a bruise.

A study into the ageing of bruises determined that the only reliable fact is that bruises with a yellow colour are more than 18 h old, and that the appearance of the other colours is less reliable (Langlois and Gresham 1991).

The following observations should be recorded for each bruise:

- dimensions;
- colour;
- pattern;
- site; and
- associated injuries.

The following observations should be recorded for each abrasion, laceration, incision and stab wound:

- nature and number of such injuries;
- site;
- dimensions including injury depth;
- pattern and shape of injury;
- whether injury is unilateral/bilateral;
- active bleeding;
- presence of foreign material in the wound;
- evidence of healing;
- suturing, dressing or plaster cast obscuring the injury;
- coexisting injury;
- associated injury; and
- whether there is any pre-existing injury.

Abrasions

Abrasions are also known as scratches or grazes, where a scratch is a linear abrasion and a graze is a 'brush-mark' abrasion. Abrasions are injuries involving only the outer layers of skin: partial-thickness tears. The skin injury of an abrasion is at the site of the impact with injuring force. Abrasions are usually linear in nature but may be curved due to fingernails or a human bite.

Lacerations

Lacerations, also known as cuts or tears, occur when the injuring blunt force causes full-thickness splitting of the skin in a ragged way. They are often associated with bruising and there may be flaps of skin due to a shearing force being applied.

Incisions

Incisions are caused by sharp cutting weapons and are seen less commonly in the genital injuries of rape and sexual assault, although the genitalia and breasts may be the target of the assailant wielding a knife or similar sharp weapon. The tissues are cleanly divided and the cut is long and less deep than a stab wound.

Stab wounds

A stab wound is a penetrating deep injury. With respect to transvaginal impalement, there is considerable risk of

damage to extravaginal sites. Identification of possible extensive injury may be difficult and would require multi-disciplinary involvement.

Thermal injury

Thermal injuries are caused by dry heat sources such as chemicals, electricity, friction and lighted cigarettes. Moist heat injuries usually refer to injuries caused by scalds.

Fracture

Fractures need careful recording of site, whether open/closed, and need for fixation or treatment.

Organ rupture

Organ rupture is uncommon, but can be life-threatening if the liver or spleen is affected. It may not be visibly obvious, so needs to be remembered if patients develop signs of shock.

Absence of Genital Injury

The absence of genital injuries should not negate an allegation of sexual assault/rape, but the presence of genital injury is thought to carry more weight in obtaining a successful conviction. In a retrospective view of case records of women from Northumbria Police area, only 22 of 83 women had genital injuries (27%) (Bowyer and Dalton 1997). It was concluded that the 'absence of genital injury should not be used as pivotal evidence by the police or CPS'. Similar incidence of genital injury was reported in a study of 440 cases of reported sexual assault, where 16% of the victims had visible genital injury (Cartwright et al 1986). By the same token, absence of genital injury in no way implies consent by the victim nor the absence of vaginal penetration by the assailant (Cartwright et al 1986).

Reasons for absence of genital injury

Reasons for absence of genital injury may include:

- verbal threats to the victim, intimidation and threats that failure to comply with the assailant's demands will result in physical injury/death to herself or another person (e.g. child);
- coercion may play a significant role in marital rape;
- force used is insufficient to produce an injury (especially in sexually active parous women);
- use, or threat of use, of a weapon;
- complainant under the influence of drugs/alcohol;
- bruises may not become apparent for 48 h;
- delay in reporting assault, allowing healing of lesions;
- use of lubricant at time of rape; and
- false allegation.

The absence of injury must also make the forensic examiner consider and include a comment regarding whether the complainant could have been threatened.

A common tactic of the barrister defending a suspect in a rape trial is not to deny that sexual intercourse between their client and the complainant took place, but rather to claim that she consented to the encounter (Cartwright et al

1986). The defending barrister may also point out to the FP and jury that there are no injuries to the victim's genitalia, and may ask the doctor how a victim of an alleged rape could escape injury unless, of course, she actually consented to intercourse, highlighting how unimpressive a case may look where there is absence of injury. Cartwright et al found that 75 victims in a review of 440 cases of reported rape showed objective evidence of non-compliance (injuries to non-genital sites) and vaginal penetration (sperm in the vagina), and only 28% of these women had sustained genital injury.

The Statement

Medical witness statement

The minimum requirement for a doctor's (professional) statement is in the form of a 'witness to the fact' document providing a basic interpretation of the findings alone. The FFLM has recommended that all FPs should have training in the production of a factual statement, and should have ongoing support with writing statements from experienced FPs (Faculty of Forensic and Legal Medicine 2008b).

Timing of statement preparation

It is a wise practice to complete a statement as soon as possible after the examination, and include an interpretation and opinion at the end of the statement, either using lay terms where possible or including a glossary of the medical terminology.

The statement should contain core data such as the examiner's qualifications, relevant experience and number of cases examined, although this can be considered an optional field for new forensic examiners. This should be followed by a summary of the history of the incident. The findings, both normal and abnormal, must be documented.

Interpretation of findings

- Causation of injuries.
- Mechanisms leading to injury.
- Degree of force required to produce the injury.
- Other possible causes for findings.
- Exclusion of unlikely causes.
- Consistency of findings.
- Opinion — using a sliding scale to describe the degree of certainty.

Interpretation of the physical findings is one of the most difficult aspects of forensic gynaecology. The legal profession, in particular, has an unrealistic expectation regarding what conclusions can be reached following a forensic medical examination, and the unwary examiner may find themselves accused of bias.

It is important to comment upon whether appearances of the genital area are normal or abnormal.

In general, when considering bruises, one should assess the site of the bruising and how this may affect the appearance of the bruise, the causation and the force of impact that might have caused the bruising. It is helpful to use a scale to describe one's degree of certainty about the likely cause of the particular injuries.

Conclusions

In preparing the conclusions, the overall causation and consistency need to be addressed so that the following aspects are covered:

- the presence of signs that support the allegation;
- whether the signs are consistent with the allegation;
- the probable causation of the injuries;
- whether or not consensual sexual activity could explain the findings;
- the effect of age and hormonal status on the genital tissues;
- the presence of any unusual injuries and the implication of such injuries;
- reasons for absence of injury should be addressed;
- suggest realistic alternative causation such as an accidental injury (e.g. streaky, linear bruising due to a watchstrap or piece of jewellery, or an ovoid abrasion due to a fall against a similarly shaped object);
- the site of injuries is very important (e.g. accidental bruising on the inner aspect of the thighs or knees is very unlikely, a more likely cause being the blunt force of an assailant's knees or thumbs being applied to separate the legs); and
- inconsistencies — the possibility of a false allegation must be entertained when preparing the opinion. Also, in interpreting any injury, the doctor must consider whether it has any features suggestive of being self-inflicted. Clues that may assist in this assessment include location of the wound (accessibility), the direction of linear (often parallel) scratches, and the sparing of sensitive areas of the body.

The conclusion should end with a sentence indicating that the statement has been 'based on information given to me to date'. Also, there should be some indication that modification of the conclusions may be necessary if further, relevant information becomes available.

Use of relevant references

The absence of genital injuries should not negate an allegation of sexual assault or rape, but it does make it more difficult to prove to a jury as the presence of genital injury is thought to carry more weight in obtaining a successful conviction. With reported rates of visible genital injury being of the order of 20–49%, it is important that the examining doctor is able to quote published data to support the statement that the absence of genital injury does not imply consent by the complainant, and that the presence of genital injury should not be required to validate an allegation of sexual assault (Cartwright et al 1986, McGregor et al 2002, Palmer et al 2004, Drocton et al 2008).

Final reminders on statement presentation

The forensic examiner should ensure that the statement has a professional appearance, and having checked the document for errors, should also make a check for areas of vulnerability to criticism. In England and Wales, there is a statutory declaration to sign and date the beginning of the statement.

Patterns of Injury

Patterns

Some female survivors of sexual assault sustain more physical injuries than others, and factors influencing the type of injury include the complainant's skin fragility. Genital trauma is more common in older women (Ramin et al 1992). Where there are multiple bruises, it is essential to undertake a collective assessment of both the bruises and any other surrounding injury in an attempt to reconstruct events. It is also important to recognize particular patterns of injury (e.g. finger-tip bruising consisting of a row or a pair of circular or oval bruises, suggesting the blunt force of gripping associated with resistance in areas such as the upper arms, breasts and legs).

Postmenopausal women

One of the factors influencing the type of injury sustained is the victim's age. Postmenopausal women only represent a small percentage of the number reporting sexual assault: 2.2% in Dallas County between 1986 and 1991 (Ramin et al 1992). There was no significant difference in the relative proportion of women experiencing non-genital injuries; trauma in general occurred as frequently in the older woman (67%) as in the younger group. This was confirmed in a later study on the effects of age and ethnicity on physical injury from rape (Sommers et al 2006).

Genital trauma is more common: 43% in the postmenopausal group compared with 18% in younger women (Ramin et al 1992). Almost one in five older women had genital lacerations. Other authors have reported an increased frequency of genital injuries in the older victim of sexual assault, and being aged over 40 years has been identified as a risk factor for genital injury (Cartwright et al 1986, Palmer et al 2004). However, no significant association between age and genital injury was found by Sommers et al (2006).

Where there is an increased genital trauma rate, it is presumably due to postmenopausal atrophy causing increased genital tissue susceptibility. It is sad to reflect that older victims tend to live alone, are often robbed and are more likely to be raped by a stranger (Tyra 1993).

Adolescent victims

A pre-existing relationship between a victim and the assailant may explain other elements that distinguish an adolescent victim from her adult counterpart (Muram et al 1995). An assessment of the epidemiology and patterns of AGI in a group of adolescents (13–17 years old) compared with women over 17 years of age showed that adolescents were more likely to be assaulted by an acquaintance or relative (Jones et al 2003).

Weapons and physical force are used less frequently where adolescent victims are involved, but alcohol and drug use is prevalent in adolescent victims (47% of cases) (Muram et al 1995). There are conflicting opinions about the frequency of physical, non-genital injuries in adolescents compared with older victims of sexual assault, but a recent study showed that adolescent victims were less likely to experience non-genital injuries than adults but had a greater

frequency of AGI (Jones et al 2003). Common sites of injury in adolescents were posterior, including fossa navicularis, labia minora, fourchette and hymen, whereas for adults, there was a less consistent pattern of AGI, although they did have fewer hymenal injuries and greater injury to the perianal area.

A significant association has been found between race (Black vs White) and genital injury, where Whites were four times as likely as Blacks to have genital injury (Sommers et al 2006). The reasons for this disparity appear to be complex, and the simple explanation of skin colour explaining race/ethnic difference in injury prevalence may suffice for the forensic examiner. However, health disparities may affect the reporting of genital injuries amongst women of colour in the USA.

Vulnerable Women

Mental health

It is important that all the professionals involved with victims of sexual assault recognize that the assault may be followed by rape-related PTSD. This is a debilitating psychiatric condition that can occur in people who experience extremely stressful or traumatic life events, and sexual assault is thought to be one of the most traumatic stressors in life. It is believed that victims attending for forensic examination may already be in the acute phase of PTSD, exhibiting shock, disbelief, anger and possibly memory blocking. The risk of PTSD among female victims of sexual assault is 2.9 times higher compared with women who reported no history of sexual assault, according to a cross-sectional telephone survey of 1769 adult female residents in Virginia (Masho and Ahmed 2007).

When attending a victim of recent sexual assault, the FP may question whether such a woman is able to give 'informed' consent to all aspects of the forensic medical examination. It may be appropriate, in this case, to complete the consent for examination and sample collection, and defer the consent to disclosure of the medical details until a later date.

A high background prevalence of mental health problems and deliberate self-harm was found in a study of 121 complainants of sexual violence at The Haven, Whitechapel (Campbell et al 2007). When mental health problems were identified, additional questions were asked. Of the female victims, 8% had learning difficulties, 21% had a past history of deliberate self-harm and 20% had a psychiatric history. Three percent of the female victims required immediate referral to the psychiatric liaison team. One must not forget that vulnerable people are at increased risk following sexual violence; indeed, a high frequency of PTSD is seen in female refugees who allege torture (Asgary et al 2006, Edston and Olsson 2007, Hooberman et al 2007).

Women with disabilities

Very few studies have examined how sexual assault patterns differ for women with disabilities, and whether a woman's disability status influences the degree and nature of the sexual violence. Study data derived from the initial encounter of 16,672 women survivors of sexual assault in Massa-

chusetts from 1987 to 1995 showed that more than 10% of survivors reported one or more disability (Nannini 2006). Among women with a single disability, a survivor who delayed seeking services for 6 months or more was more likely to have a mental health disability. Women with disabilities have been shown to have four times the odds of experiencing sexual assault in the past year compared with women without disability, according to a study in North Carolina (Martin et al 2006). A retrospective longitudinal study of 6273 non-institutionalized women participating in the National Violence Against Women survey in the USA found that women with disabilities that severely limit activities of daily living are four times more likely to be sexually assaulted than women with no reported disability (Casteel et al 2008).

There are even fewer studies concerning refugees who allege that they have been sexually assaulted as victims of torture. In Sweden, the records of 63 female victims of torture were studied (Edston and Olsson 2007). Rape, often both anal and vaginal, several times and by different persons, was reported by 76% of the women. Physical abuse by use of blunt force was alleged by 95%. In a study in the USA, 89 asylum seekers/torture survivors from 30 countries were assessed in an urban primary care clinic, and 7% of cases alleged that rape was the means of abuse (Asgary et al 2006). The authors point out that physicians evaluating torture survivors should be trained in identification and documentation of torture. This is particularly important where sexual violence as a means of torture is alleged.

Migrant women

In the UK, migrant women may be reluctant to seek help and advice, or approach the criminal justice authorities if they perceive that their immigration status might be put at risk by coming forward. In addition, such women may not be aware of the interpreter services that exist for women seeking help with health-related problems. Worldwide, the higher vulnerability of migrant women to sexual abuse and violence is known to place them at risk of STIs and mental health problems associated with sexual violence. Migrant women face sexual abuse by employers in receiving countries, and from personnel in refugee camps (Carballo et al 1996). Migration also fuels the sex tourism industry in countries as diverse as the Netherlands and Thailand.

Court Proceedings

Victim in court

The victim may be called to give evidence as a witness at a Crown Court if the attacker pleads 'not guilty'. In addition to the support of the police officers and counsellors involved, they can also seek the support of the Crown Court Witness Service. Arrangements can be made for the complainant to visit the court before the trial, and information on police and court procedure, liaison with other organizations on behalf of the victim, and assistance in application for compensation from the Criminal Injuries Compensation Board can be provided.

Pretrial conference

The examining doctor will be expected to read through the notes carefully and should expect to be called to a pretrial discussion, in their capacity as a professional or an expert prosecution witness, with the reviewing lawyer, CPS caseworker, police officer and counsel for the prosecution (barrister). It is important that the examining doctor has access to the committal papers (witness statements, transcripts of taped interviews and the defence statement), the complainant's forensic test results and the defence medical expert's report, and is able to discuss this opinion with counsel.

Doctor in court

The doctor should be familiar with the courtroom lay-out (in particular, the location of the witness box, judge's bench and the jury) and the Crown Court etiquette, such as addressing the jury at all times, and should decide ahead of time whether to make a solemn affirmation or swear an oath.

The defence usually asks for an independent medical expert report and they will have access to copy statements from the complainant, the examining doctor and the defendant, and transcripts of interviews. The defence may also request the contemporaneous medical notes.

Examination-in-chief

The examining doctor may be called to court as a professional witness to help the court to establish the facts. The purpose of the examination-in-chief is for the FP to make their evidence clear to the judge and jury. The reviewing barrister establishes the professional witness's name, qualifications and expertise, and then asks for confirmation of the details of the statement. Addressing the jury, the doctor will be asked by the counsel for the prosecution (reviewing barrister) to describe what was found at the time of the examination. The doctor is usually asked to give an opinion regarding the possible causation for the findings.

Cross-examination

Counsel for the defence (opposing barrister) then conducts the cross-examination of the professional witness, asking questions to probe particular issues in the professional witness's statement in order to identify any contentious issues of fact or opinion. The defence barrister's role is to draw the professional witness's attention to any deficiencies in the evidence that will favour their client.

Re-examination

When cross-examination is complete, the prosecuting barrister has the opportunity to re-examine, clarifying any issues raised. No fresh material can be raised at this point. The judge, too, may wish to ask further questions or summarize what has been said.

Expert witnesses in sexual assault

Medical evidence is an important factor in the prosecution of rape offences, but it is felt that its evidential worth is not

always properly understood by the prosecution. 'It is vital that the quality of the expert evidence relied upon to support the investigation and prosecution of rape is sound. If it is flawed then challenge by the Defence is inevitable' (H.M. Crown Prosecution Service Inspectorate 2007). The FFLM believes that expert evidence should only be sought from FPs who have gained a postgraduate qualification in clinical forensic medicine.

The GMC in 'Acting as an Expert Witness' emphasizes the importance of 'understanding and adhering to the laws and codes of practice that affect your work as an expert witness. In particular, you should make sure that you understand:

- how to construct a court-compliant report
- how to give oral evidence
- the specific framework of law and procedure within which you are working'.

Expert witness statement

The concept of a two-stage report in a single contact case of sexual assault/rape has been proposed, and the philosophy of such an approach is to improve the successful conviction rate and to provide a structure that is supportive to relatively inexperienced forensic examiners. The initial statement made by the examining doctor who is a professional witness is a factual account of the findings, and for those cases likely to proceed to court, a second 'expert' statement might be commissioned. The initial forensic examiner might wish to end their initial conclusion with the following comment: 'Should it appear likely that this case would proceed to court, a second, more detailed statement will be required. Either:

- I am prepared to provide that statement; or
- An expert forensic examiner will prepare this statement'.

The FFLM recommend that all FPs should annotate their professional statements with 'this is a professional witness statement of fact. I am able/unable to provide expert opinion evidence in relation to this matter/and would be happy to do so on supply of all relevant documents' (Faculty of Forensic and Legal Medicine 2008b).

As an expert, the doctor's legal position is one of an advisor to the prosecution on matters which are outside the experience of the general public. The expert should have access to the fullest possible picture in order to give the best advice and opinion. Accordingly, the expert should have sight of all relevant statements, a record of the defendant's interview, relevant medical records and the results of the scientific tests. An expert should prepare their statement based upon their analysis of the case, and provide an opinion with the assistance of the examining doctor.

It is recognized that an important factor in the development of expertise is the building of case experience, and so within the REACH organization, it has been established that an 'expert' forensic examiner is one who has examined 20 rape/sexual assault cases and has been actively involved as a FP for at least 2 years. In addition, the expert will have undertaken appropriate training and be an 'accredited' FP. The term 'accredited FP' implies that the doctor is willing and able to provide an expert statement. An 'accredited FP' is under no obligation and the provision of an expert opinion is optional to those experienced enough to do so. Such a

two-tier system may prove costly, but with UK conviction rates running at approximately 6.5%, this novel approach may assist the CPS in their assessment of the strength of a particular case (McGregor et al 2002).

Conclusion

There is growing international concern about the low conviction rate for rape. Forensic examination services, clinicians and the judiciary are jointly involved in addressing the attrition rates in sexual assault cases in the UK. The reporting of rape can act as a gateway to other services, and this is particularly important for vulnerable women such as those with mental health problems. The criminal justice system has introduced initiatives in an attempt to improve the response to rape cases, but it is also important to recognize that there is a need for improvement in the clinical/forensic management of sexual assault cases including:

- improved levels of support for complainants at all stages;
- improved levels of communication between the FP, counsellors, police, CPS, general practitioner and complainant;
- continuing improvements in evidence gathering and report writing;
- recruitment to forensic gynaecological training programmes and hence to forensic examination teams; and
- continuing multidisciplinary education for all concerned in the care of rape victims.

In addition, it is very important that there is rapid implementation of the new laws that aim to protect the victims of sexual assault, especially vulnerable witnesses in rape trials, and that research programmes are established to gain a better understanding of why there is a high rate of charge reduction and why complainants withdraw their allegations.

KEY POINTS

1. There may be many reasons for failure to report sexual assault.
2. Consent to forensic medical examination differs from the standard consent forms and must accommodate details about disclosure of evidence.
3. The estimation of the age of a bruise should be avoided.
4. The absence of genital injury does not imply consent by the victim.
5. Following the examination, the victim should be offered appropriate medical advice, counselling and follow-up.
6. When interpreting the findings, the professional witness should comment upon whether the appearances are normal or abnormal, and describe their degree of certainty about the likely cause of any injuries.

PREVALENCE	1003	SEXUAL VIOLENCE IN WAR	1006
REPRODUCTIVE HEALTH CONSEQUENCES	1003	SUMMARY	1007
MANAGEMENT OF PROSTITUTION	1005	KEY POINTS	1007

Background

Violence against women is prevalent worldwide and is most commonly inflicted by men. Such violence takes many forms in different settings, sometimes legally sanctioned by the state and/or morally sanctioned by the society within which it occurs. However, while women can be at risk in many settings, the most common form of violence against women is domestic violence or abuse inflicted by the woman's partner or ex-partner, and the violence usually takes place in the home.

While the term 'domestic violence' could imply violence or abuse from either partner in a heterosexual or homosexual relationship, a United Nations report in 1995 recognized that the most common manifestation is violence against women by male partners (United Nations 1995). In the 1992 British Crime Survey (Mayhew et al 1993), domestic violence constituted the single largest category of assaults, with 80% directed against women. In the USA, it is estimated that 95% of battered partners are women (Jones 1997). The United Nations report highlighted the range of types of physical abuse suffered worldwide by women at the hands of their partners, including battering, marital rape, dowry violence, domestic murder, forced pregnancy, abortion, sterilization and forced prostitution. During pregnancy, violence may also cause miscarriage or fetal injury and/or death. Women also experience non-physical abuse in the form of psychological, emotional and economic abuse.

Domestic violence or abuse is difficult to define but a definition such as 'the psychological, emotional and economic as well as physical and sexual abuse of women by male partners or ex partners' (Scottish Needs Assessment Programme 1997) indicates the range of ways and circumstances in which women can be abused by their partners. Thus, while society's perception is that the greatest risk of violence comes from strangers outside the home, statistics confirm

that this is not the case for women. Nevertheless, in addition to beating of a wife by her husband, violence against women includes other types of abuse such as abortion of female fetuses, female genital mutilation, forced prostitution by non-partners, rape (including rape and sexual violence as a war strategy) and murder. Women are also at risk of violence or abuse from any relationship or interaction with men in which sex is a factor; thus, while forced prostitution by a partner is itself a form of partner violence, women working as prostitutes, whether for a partner, another man or independently, are also at risk of violence from their clients. However, it is important to recognize that prostitution encompasses a wide spectrum of circumstances; while violence may occur as part of the practice of prostitution, it does not follow that all prostitution constitutes violence against women.

Violence against women is important to those providing reproductive health care. Women experiencing or at risk of violence are particularly vulnerable during pregnancy. Domestic violence often starts or escalates during pregnancy, and since the circumstances that drive a woman to commercial sex do not change because she has become pregnant, prostitution continues throughout pregnancy. Violence during pregnancy has obvious implications for the health of both mother and baby, and consequently has relevance for those providing maternity care (although recognition of this has been slow to develop). The relevance of violence to non-pregnant women is often only viewed in terms of rape. However, violence can cause or affect other gynaecological conditions, as well as having implications for other types of reproductive health care. It is therefore important to recognize that the entire spectrum of violence against women is of relevance to all aspects of reproductive health care.

The last 20 years has seen a worldwide increase in recognition of the health consequences of violence against women and the large spectrum of types of violence. This was accompanied by considerable research, the findings of which are

supported by ongoing work in this area (Tjaden and Thoennes 2000, Watts and Zimmerman 2003).

Prevalence

The true prevalence of violence against women is difficult to determine. This is largely because of underidentification, but also because prevalence will depend on the definition of violence adopted. Studies in many countries have produced a range of estimates of prevalence for various categories of domestic violence and/or abuse. While the figures vary according to the type of abuse recorded, all are likely to be underestimates. The World Health Organization's Multi-country Study on Women's Health and Domestic Violence Against Women (2005) surveyed 10 countries, representing diverse cultural settings including urban and rural areas within the same country. It obtained information from over 24,000 women. The prevalence of women who reported episodes of domestic violence ranged between 15% and 71%, with the greatest amount of violence being reported in provincial settings in Bangladesh and Peru. In countries where large cities and rural areas were studied, partner violence was consistently higher in provincial settings. Women's attitudes to violence and acceptance also varied; violence was condemned in urban areas, whereas in some rural areas, violence was accepted and justified, especially in situations such as female infidelity.

In the USA, estimates ranged between 2 million (United Nations 1995) and 4 million battered women, with 2000 women murdered each year (30% of female homicides) in association with battering (Jones 1997). In a Canadian survey of 12,300 women, 29% reported that they had experienced violence from a current or previous marital partner since 16 years of age (Johnson and Sacco 1995). In the UK, the Home Affairs Select Committee Report on Domestic Violence (1993) concluded that domestic violence is 'common'. While the 1992 British Crime Survey (Mayhew et al 1993) found that 11% of women reported physical violence in their relationships, a 1993 crime survey in Islington, London (Mooney 1994) found that one in four women reported a lifetime experience of domestic violence. In a study of 930 women in San Francisco, 12% reported rape by their husbands (Russell 1982), while in a UK study of 1000 women, one in four reported that they had experienced marital rape. The prevalence of violence to prostitutes from both clients and pimps (regardless of whether or not the latter is the regular sexual partner) is also difficult to assess. Nevertheless, its occurrence is well recognized by those who work with prostitutes, although not necessarily by the criminal justice system whose response has often been inappropriate (Kennedy 1993).

The abuser, the abused and patterns of abuse

Many of the forms of violence described above occur in the UK. It is widely believed that such violence is largely confined to the lower social classes, but this is a misconception. Domestic abuse occurs across the social spectrum, and is inflicted by men who are not necessarily mentally ill but who have a range of personality defects (Mezey 1997). Various factors may coexist with violence either as cause or

effect. While abuse occurs throughout society, socioeconomic deprivation, unemployment and lack of education are cited as precipitating and perpetuating factors (Kennedy and Dutton 1989). Whatever the precise relationship, women from backgrounds of socioeconomic deprivation may have fewer resources and fewer options for dealing with the abuse.

Problem drug and alcohol use are often thought to be linked to abuse and are often offered as an excuse or justification. While men with substance misuse problems may be more likely to abuse their partners, this may not be because they are intoxicated, and they may do so while sober. The 1996 British Crime Survey showed that intoxication of the perpetrator with alcohol or drugs was less common in the case of domestic violence than in stranger and acquaintance violence (Mirrlees-Black et al 1996). Additionally, abusive men may cite substance misuse by the partner as the cause or justification for their abusive behaviour. While there is no evidence to support this, it is true that women suffering abuse may develop drug and/or alcohol problems as a consequence of the abuse (Stark and Flitcraft 1991, Plichta 1992).

Women working as prostitutes experience poverty and many have drug or alcohol problems. Many such women will have a history of abuse, including sexual abuse by a family member, partner or other person. Their partner may also have problem substance use financed by the prostitution. The more chaotic the woman's lifestyle, the greater her financial need, the less she is paid, the more clients she has to service to raise the necessary money, the more dangerous the circumstances in which she must work and the greater her exposure to the risk of violence.

However, while associations with various factors do exist and some groups of women are consequently at increased risk of violence, it is important to remember that these factors are not necessarily obvious. Moreover, there is no typical abuser and no typical abused woman.

Reproductive Health Consequences

Women who experience violence are more likely to suffer a number of consequences relevant to reproductive health services. More than 30% of domestic violence begins during pregnancy (CEMACH 2004), and more than 14% of maternal deaths occur in women who had told their health professional that they were in an abusive relationship (CEMACH 2007).

During pregnancy, the injury sites include breasts and abdomen with consequent risk of injury to the fetus, including miscarriage, premature delivery and fetal death (Mezey and Bewley 1997). Women who have experienced violence are more likely to suffer miscarriage (Stark and Flitcraft 1996). Pregnancy, genital tract infections and genital tract injury are possible consequences of sexual violence, while other persistent gynaecological problems, especially abdominal pain, may be the presentation of abuse. Such women may find it difficult to undergo pelvic examination.

Obviously, in all of these situations, the converse does not apply and not all women with such problems or difficulties have been abused. Equally, many women who have been

abused demonstrate no obvious problems or stigmata which might indicate a history of abuse.

Presentation

Women may present because of violence in a number of ways. They may specifically report physical violence, including rape (see Chapter 65), or may present for treatment of physical injuries sustained (with or without admission of the circumstances), in which case the setting is most commonly the accident and emergency department or the general practitioner's surgery. Injuries sustained include bruises, cuts, fractured bones and internal injuries (Dobash and Dobash 1980). In pregnancy, injuries include maternal rupture of the uterus, spleen or liver; placental abruption; premature spontaneous rupture of the membranes; miscarriage and fetal death (James-Hanman and Long 1994). Other indicators of domestic abuse are late booking and poor or non-attendance at antenatal clinics, repeated attendance during pregnancy with minor ailments and unexplained admissions. Previous reports of maternal deaths involving domestic abuse recommend that all women attending maternity services should be asked specifically about domestic abuse and given the opportunity to disclose this information.

Abused women may present later with psychological problems such as anxiety, depression (including suicide attempts), and drug or alcohol problems (Stark et al 1979, Hillard 1985). They may present to reproductive health services, including obstetric and gynaecology departments, in various ways. Immediate problems prompting attendance include obstetric complications and injuries, including genital tract injuries. Women may present with clinical problems secondary to the violence, such as possible genital tract infection, the need for emergency contraception or subsequently with a pregnancy. Many women only present later with chronic gynaecological problems, such as chronic pelvic pain.

Violence, domestic or otherwise, may therefore be highly relevant to women's attendance at obstetric and/or gynaecology services. However, irrespective of the immediacy or directness of the association, and no matter how obvious the markers, the possibility will not necessarily be recognized. Moreover, women who present in these ways rather than with a specific complaint of violence and/or rape, whether or not the perpetrator is the partner, are unlikely to admit the abusive circumstances unless asked directly. Violence and/or abuse may therefore not be identified unless healthcare workers ask; since the occurrence of abuse is often not suspected in such situations, routine direct enquiry will be necessary for effective identification and management of this problem.

Identification

Violence against women is often not identified within healthcare services because women may not volunteer the information and they are often not asked about it. In one study of 290 pregnant women in which 23% reported past or present battering, none had been questioned about violence by any healthcare providers (Helton et al 1987). Many women do not want to involve authorities such as the police or law courts, and the authorities may not consider the

problem within their remit; indeed, they may not even consider it a problem at all. In the UK until 1829, a man had a right to 'chastise' his wife provided he used a stick 'no thicker than his thumb'. The possible existence of rape within marriage was only recognized in Scotland in 1989 and in England and Wales in 1991. Since commercial sex is widely viewed as voluntary, with the women morally responsible, violence against prostitutes is often considered an unavoidable risk of this activity that does not justify legal pursuit. Even when the violence extends to murder, this is seen as different from murder of a 'respectable' woman (Kennedy 1993).

Women who experience violence from a partner often feel ashamed. They also often feel that they are at least partly to blame, and must have deserved the abuse in some way. They are also afraid that if they disclose the abuse to a third party, their partner will find out and they will suffer even more violence. Similarly, women working as prostitutes are often ashamed of their involvement in prostitution and do not want to admit it. While not necessarily believing they deserve violence, they may feel that their activities invite it and they therefore bear some responsibility. Whatever their feelings, however, most prostitutes believe that a report of violence would not be received sympathetically by the relevant services, would not lead to an effective response and would therefore be pointless. Similarly, many women suffering partner violence do not expect a sympathetic or helpful response from services. Nevertheless, evidence shows that despite their reluctance to raise the subject and report the violence, and despite the inadequacy of responses, women who suffer violence or abuse want to be asked about it and to be given an opportunity to disclose it. In one American primary care survey, 75% of women favoured routine enquiry about physical abuse, and 97% of female and male respondents said that they would answer truthfully if asked directly. However, only 7% said that they had ever been asked (Friedman et al 1992).

There are various reasons why healthcare workers do not ask about violence (Sugg and Inui 1992). They may be unaware of the possibility of abuse or think it is rare; they may not perceive violence, domestic or otherwise, as their responsibility; or they may be unwilling to ask, either because they feel they lack the necessary skills, because they fear they may cause offence or because they are afraid of broaching a problem that they would not have the time or the knowledge to deal with. In many areas, there are insufficient or inadequately resourced support services to which women could be offered referral. The advice given is often limited to a recommendation to leave the batterer, and frustration is expressed when women do not follow this advice. Consequently, many healthcare workers feel unhappy asking about abuse and would only do so if there was obvious evidence of abuse. Any injury might be expected to raise suspicion, but injuries at various sites, of different ages and for which no good explanation is offered should indicate possible abuse. However, even in the presence of obvious markers of abuse, healthcare workers do not always make the connection and, whether consciously or unconsciously, do not recognize the possibility of abuse or enquire about it. Moreover, many abused women will not demonstrate any of the recognized markers, and not all women with these markers will have been abused.

Risk markers are therefore insufficiently sensitive or specific, and should not be used as a basis for selective enquiry. As well as being ineffective, selective enquiry (if obviously selective) can also be offensive regardless of whether or not the woman has suffered abuse. Any awkwardness on the part of the healthcare worker will be conveyed to the woman. The way the question is posed is therefore important. A statement such as 'I know this probably doesn't apply to you but we have to ask everyone' gives a clear indication of the 'correct' response and does not encourage disclosure. Identification of violence is important in reproductive health care; given the nature of services provided, it is entirely appropriate to take an adequate sexual and social history, including direct enquiry about violence and abuse in all cases.

Management of abuse

While all women should be asked about abuse, the circumstances must be conducive to disclosure. Privacy is essential and all women should have at least part of any reproductive health consultation conducted on a one-to-one basis with the doctor, nurse or midwife. The presence of a partner who is reluctant to leave will not only prevent enquiry but may be an indicator of abuse. There should be recognition that not all abused women will admit this on routine enquiry; a negative response will not preclude violence, and if there are strong suspicions, some support can often be provided in the absence of an explicit admission. Disclosure may then occur during a later consultation.

All women presenting in pregnancy should be asked about the circumstances of the pregnancy; whether the pregnancy is planned, intended and/or wanted; their relationship with their partner (or man who accompanies them) and whether he is the baby's father. In this context, it is simple to ask the woman about the quality of the relationship and specifically whether her partner has ever been violent to her. She should also be asked whether anyone else has ever been violent to her and whether she has ever been forced to have sex with someone against her wishes. Women presenting with a gynaecological problem should similarly have a full sexual history taken. All women, pregnant or non-pregnant, presenting for any type of reproductive health care should have a social history taken. This should include questions about lifestyle, including use of tobacco, alcohol and illicit drugs, all of which can directly affect reproductive health. Women who disclose illicit drug use should be asked how this is financed, including specific enquiry about involvement in commercial sex.

There are several important aspects to management (Heath 1992). It is important that a woman who discloses a history of violence is reassured that she is believed and that she is not responsible for nor deserving of the violence. In the reproductive health setting, management of the relevant injuries or medical problems with which she presents will be a priority (management of women presenting with a present history of rape or sexual abuse is described in Chapter 65), but the healthcare worker's responsibility does not end there. Details of the violence together with the woman's circumstances should be elicited, and an assessment should be made of immediate risk to the woman and/or her children or others in her immediate circle. The information she

provides should be documented accurately together with details of examination findings, including injuries if present and any treatment given. Such information may be required for future legal action. She should be reassured that any information she provides will be treated with confidentiality, but there should also be discussion about the meaning of and limits to confidentiality. Should the healthcare worker envisage having to disclose the information, such as to ensure child protection, this should be discussed with the woman at the outset.

There should be discussion with women experiencing domestic violence or abuse about the possibility of leaving the abuser. Information including contact telephone numbers should be provided about residential and non-residential services for women experiencing violence, as well as availability of any other alternative accommodation. However, it is important to recognize that it is often not feasible for women to remove themselves from the situation. For example, they may be financially, emotionally or otherwise dependent on the abuser, or it might not be possible for them to take their children with them for various reasons. Moreover, when the woman appears to be at significant and imminent risk of further violence, leaving the situation may increase that risk; women are especially likely to suffer significant injury or even be killed when they leave a violent domestic environment (Browne 1987, Geberth 1992). It is therefore essential that women are reassured that there is recognition of and sympathy for the limitations to their options, and are not given the impression that they are expected to leave or will be considered stupid or weak if they fail to do so.

Regardless of their circumstances or chosen action, women should be provided with information about services and also the offer of direct referral. Where specific problems (whether cause or effect) are identified, such as mental health or substance misuse problems, appropriate referral for specialist management will be helpful even if it does not resolve the problem of violence. Moreover, problem drug and/or alcohol use can have direct effects on reproductive health, which merit treatment of the problem in their own right. This is therefore discussed later.

Management of Prostitution

At present, approaches to legislation differ across countries with regards to prostitution. In the UK, a Home Office consultation paper, 'Paying the Price' (Home Office 2004), prioritized the needs of communities in preference to the health and safety of sex workers. This led to publication of the Coordinated Prostitution Strategy (Home Office 2006) that focuses on criminalization of prostitution. In a Canadian study, Lowman et al found that a criminalized system increased the risks to vulnerable women, and they were more likely to be vulnerable to predatory and premeditated forms of violence in comparison with women working within a legalized framework where violence was often situational (i.e. regarding non-payment for services) (Lowman 2000).

In contrast to the UK, countries such as New Zealand and the Netherlands have focused on decriminalizing sex work; a decision based on a duty to protect sex workers. The

Prostitution Reform Act 2003 in New Zealand decriminalized sex work and improved workers' health, safety and job satisfaction. Women found that they could use the law to encourage condom use and reduce their risk of sexually transmitted infections, and were more confident at refusing clients who did not adhere to this.

Criminalizing prostitution forces the most vulnerable women away from health services, and increases the risk of violence and other health consequences.

Women experiencing violence in non-domestic settings receive similar support. Women seen at reproductive health services who admit involvement in commercial sex will invariably have attended for some other reason and the presenting problem will obviously need to be dealt with. Nevertheless, an admission of prostitution should prompt a full relevant history, including details of type of services offered and clients buying them. Sexual behaviour and consequent risks, together with relevant signs and symptoms, should be explored. In the obstetric context, women engaging in commercial sex will often claim that paternity is not in doubt and the pregnancy is definitely to their partner. However, clients often pay more for unprotected intercourse and a carefully taken sexual history may indicate that such confidence is misplaced. Nevertheless, such self-deception by a woman and/or her partner, whether conscious or unconscious, is often an essential coping strategy, so it is not necessarily helpful to comment on it unless specifically asked to do so, when it should be discussed with the woman on her own. Even if not explicitly admitted, however, uncertainty or concern about paternity may increase the risk of violence to the woman from her partner. It is, of course, entirely reasonable and appropriate to discuss strategies for risk reduction in terms of sexually transmitted infections and unplanned/unwanted pregnancies with non-pregnant women involved in prostitution. In this context, it would also be appropriate to discuss possible paternity problems if the woman is not pregnant but keen to conceive to her partner. Preconception counselling about risks to a pregnancy from sexually transmitted infections (including bloodborne viruses such as human immunodeficiency virus) would also be desirable in this situation.

Women engaged in commercial sex will escape the consequent violence by ceasing prostitution. For those women whose prostitution is directed and controlled by their sexual partner, this may be achieved by leaving the partner as in other domestic abuse situations; however, for similar reasons, this may be difficult or impossible. In addition, some such women and many working independently will have to continue working because of their own financial needs. There is a social hierarchy of prostitution. At the upper end of the market, in saunas and other indoor settings, there is less risk, often less financial pressure but greater financial rewards. At the more risky, lower end of the market, financial need is often greater or more acute but income is lower. Amongst the most vulnerable women working on the streets, factors such as problem drug and/or alcohol use that necessitate prostitution are also much more common. Nevertheless, all women engaged in prostitution, regardless of the circumstances, are at risk of violence. An approach similar to that described for domestic abuse should be adopted. An adequate history and examination are essen-

tial, as is accurate documentation of relevant information. Immediate healthcare needs should be assessed and appropriate management instigated; in this situation, the presence of any genital tract trauma or infection, whether the woman is pregnant, and consequently whether she requires maternity care, a termination of pregnancy, effective contraception or preconceptual care.

While some women working as prostitutes might be able to leave the violent situation by leaving a violent partner or pimp for whom they were earning money, most would only be able to stop prostituting if their own financial needs were resolved. For many, this would require effective management of their drug or alcohol problem.

Management of Problem Substance Use

Problem drug and/or alcohol use is often associated with poor nutrition which, in turn, may cause amenorrhoea. Heroin use can also cause amenorrhoea with or without anovulation. Methadone substitution therapy improves social stability and general health, including nutrition; commencement of therapy is often followed by return of fertility which can precede return of menstruation.

Many drug-using women incorrectly assume that their amenorrhoea indicates infertility, but they must be warned this is not so and provided with effective contraception if they do not want to become pregnant. Conversely, however, drug-using women who experience difficulty in conceiving should be advised that stabilization of their drug use, and consequently their lifestyle, with methadone substitution therapy where appropriate will increase their chances of conception. Such measures would also improve the baby's health as well as the mother's parenting abilities. This advice also holds true for their partners, since reduced sperm motility is often observed in association with use of sedative drugs including benzodiazepines and opiates/opioids (including methadone). Although the precise functional significance of this is uncertain, in the absence of successful conception, it seems reasonable to give both partners general advice about reduction in levels of drug use, and for those on substitute medication, to recommend stabilization at the lowest level compatible with stability.

Management of the drug problem *per se* is obviously not the clinical responsibility of reproductive healthcare professionals. However, if such a problem is identified, whether incidentally or in association with prostitution, violence or reproductive health problems, women should be given appropriate information about possible effects on pregnancy, fertility and effective contraception if indicated. This should be provided together with information about specialist services and the offer of referral.

Sexual Violence in War

The use of sexual violence as a strategy in war has been observed and reported by healthcare workers, humanitarian organizations and others working in such settings (Shanks et al 2001). Women who have experienced such violence may move to other countries as refugees or asylum seekers, and may then present to healthcare workers who do not

have direct experience of such problems. Refugees presenting for reproductive health care may have experienced violence; their trauma may be exacerbated by being in a culturally unfamiliar environment, possibly without the support of family or friends, often with language and communication difficulties, and encountering healthcare workers who are unaware of or have no understanding of their previous circumstances and experiences. Some such women may be in the country illegally or awaiting the outcome of an asylum application. They may consequently be unable or afraid to access services, or to admit or discuss their problems when they do so. Similarly, other Black or ethnic minority women may be reluctant to seek help because of previous experience of racism from public services or institutions (Mama 1989), and expectation of repetition and/or fear of deportation. They may also have problems in accessing services or obtaining financial support, making it even more difficult for them to leave an abusive partner.

Summary

There is now a wide range of literature on various aspects of domestic abuse. There is increasing recognition of the need to acknowledge the impact of abuse on health, the need to deal with the problem effectively and the need for adequate training to do so. There is also recognition that this requires a multidisciplinary approach. These issues have been addressed strategically at national level (Department of Health 2000, Scottish Executive 2000). The British Medical

Association (1998) has considered the problem of domestic violence in relation to health and health care in general, while in common with many other professional bodies, the Royal College of Obstetricians and Gynaecologists has dealt with the issue from a specialty viewpoint and examined domestic violence in the context of reproductive health (Bewley et al 1997).

Violence against women is common and is relevant to all aspects of reproductive health care. Women are often reluctant to admit that they have experienced abuse, but most want to be asked about it and to have an opportunity to discuss it. While there are some indicators that indicate the possibility of abuse, they are insufficiently sensitive or specific to form the basis for selective enquiry. All women presenting for any type of reproductive health care, but especially pregnant women, should have a full sexual and social history taken which includes routine direct enquiry about violence or abuse from their partner or other individual.

Women who volunteer a history of abuse should have their experience validated. In addition to treatment of the immediate health consequences, they should have their current situation and level of risk assessed and be given information about available services, including the offer of direct referral. Limitations of options, including difficulties in removing themselves from the abusive situation, should be recognized. Careful documentation is essential for future use, including possible legal action. Effective management of this problem requires not only adequate availability of suitable services, but adequate training of healthcare professionals. Both require adequate resources.

KEY POINTS

1. Most violence against women is inflicted by men, most commonly partners or ex-partners, and usually occurs in the home.
2. Domestic abuse occurs throughout the social spectrum, but women from disadvantaged backgrounds may have fewer resources to deal with it.
3. Abuse experienced by women may be physical, psychological, emotional or economic.
4. Women are at risk of violence in any situation involving sex, including commercial sex which carries a risk of violence from both partners (and/or men controlling their prostitution) and clients.
5. Domestic abuse often begins or escalates during pregnancy.
6. Domestic abuse has gynaecological and obstetric consequences, and should therefore be addressed by those providing reproductive health care.
7. Mental health and behavioural problems, including depression and substance misuse, are more commonly effects of domestic abuse rather than causes.
8. Markers of abuse are insufficiently specific or sensitive to be used as indicators for enquiry, and all pregnant women should be asked routinely about domestic abuse.
9. Healthcare workers require training in social history taking, identification and management of domestic abuse.
10. The possibility that healthcare workers may themselves be experiencing domestic abuse must be borne in mind.

Introduction

Lesbian and bisexual women come from all walks of life: they may be old or young, disabled, Black and minority ethnic, living in poverty or living in rural areas. Despite this, some health professionals continue to believe that they have no lesbian or bisexual patients. Recent government figures estimate that there are 1.6 million lesbian and bisexual women living in the UK, comprising 5% of the female population (Department of Trade and Industry 2004). Studies suggest that up to one-third of lesbian and bisexual women have children, they may be more likely to have had a university education, but there is conflicting evidence about their income relative to heterosexual women (Fish 2006).

It is increasingly recognized that obstetricians and gynaecologists know little of their distinctive health concerns. Although notions persist that homosexuality itself is a disease, many healthcare professionals otherwise believe that there are no differences in lesbian and bisexual women's health from that of women in general; there is often a perception that sexual orientation is a private matter which is irrelevant to the health consultation (McNair 2003). Over the past 20 years, research has suggested that the health of sexual minority women differs in key ways: in their health behaviour, health risks and experiences of health care. Lesbian and bisexual women are less prevention oriented and avoid routine screening tests, such as cervical cytology and mammograms. For these reasons, sexual orientation has been recognized by the Department of Health as a ground for health inequalities (Fish 2007). Sexual orientation is unique among the six equality strands (i.e. 'race', gender, age, disability and religion) in not being included in the UK census; this omission has contributed to a lack of research

in sexual orientation and health, and a dearth of statistics about their demographic characteristics. Healthcare professionals may also lack specific knowledge of lesbian and bisexual women's needs and be unable to provide relevant health information (Hughes and Evans 2003, McNair 2003).

Evidence suggests that discriminatory treatment is now less common in health care (Solarz 1999). Lack of understanding and the personal discomfort of health professionals, however, often mean that lesbian and bisexual women have a differential experience of health care. Doctors are sometimes uncomfortable in providing care to sexual minority patients or embarrassed to ask questions relating to sexual behaviour (Hinchliff et al 2005). Good medical practice (General Medical Council 2006) and the desire to provide optimal health care requires health professionals to be informed about the continued barriers to health care and of differences in health risks, to be sensitive to historical stigmatization, and to be aware of issues of cultural competence with sexual minority women (Mayer et al 2008).

This chapter aims to contribute to meeting the gap in the knowledge base about lesbian and bisexual women's obstetric and gynaecological concerns.

Social Change

The introduction of the 2007 Equality Act (Sexual Orientation) Regulations offers the protection of equal treatment in public services, including the National Health Service (NHS). Current policy offers possibilities for improvement in the health of lesbian and bisexual women as legislation prohibits discrimination in health services and means that they can neither be refused care nor receive a lower standard of care. The most common response has been to overlook lesbian and bisexual women as a patient group; they have often been

invisible patients within health services, and their needs have been poorly understood. However, increasingly, their health issues are receiving attention from clinicians, other health professionals and policy makers. The Department of Health in England and Wales is working to promote inclusive services and reduce health inequalities for lesbian, gay, bisexual and transgender people; sexual orientation is included in current efforts to mainstream equality and diversity in health care (e.g. the Pacesetters Programme), and the General Medical Council has published guidance for the protection of lesbian, gay and bisexual people as patients (General Medical Council and Stonewall 2007). However, these initiatives have not been consistently implemented or acknowledged across the NHS.

The Medical Model

In biomedical accounts, lesbian health has been located within a sickness paradigm (Burns 1992). The assumption that lesbianism itself was caused by a biological, hormonal or psychological deficiency meant that the principal concern of medical professionals was to find a cause or cure. The illness model in mental health derives from assumptions that heterosexuals are normal and mentally healthy, while lesbians are impaired or abnormal in their psychological functioning (Peplau and Garnets 2000).

The aetiology of lesbianism has been variously attributed to hormonal (Veniegas and Conley 2000), biological (Terry 1990) or mental health differences (Peplau and Garnets 2000). Studies have looked for a biological origin to sexual orientation (Bogaert and Friesen 2002). Other researchers have suggested deficiencies evident in a masculinized finger-length ratio (Williams et al 2000); cerebral functioning (Rahman et al 2006); inner ears, leading to hearing loss in comparison with heterosexual women (McFadden and Pasanen 1998); and impairments in psychological functioning (Garnets and Peplau 2000). Lesbianism was widely considered a pathological condition in need of treatment, and included as a mental disorder in the Diagnostic and Statistical Manual. Until the early 1970s, lesbians underwent electric shock aversion therapy, oestrogen treatment and psychoanalysis aimed at curing their homosexuality in NHS hospitals in the UK (Smith et al 2004). Following intensive lobbying by lesbian, gay and bisexual rights groups, being lesbian (or gay) was declassified as a mental disorder by the American Psychiatric Association in 1973, removed from the World Health Organization's International Classification of Diseases in 1992, and the recommendation to convert lesbians to heterosexuality was no longer included in the guidelines of the American Medical Association from 1996 (Council on Scientific Affairs, American Medical Association 1996).

Attitudes in Health Care

Sexual behaviour between women does not result in any unique health problems, and lesbian and bisexual women experience broadly the same range of obstetric and gynaecological conditions. However, the medical model had considerable influence upon the attitudes of healthcare professionals;

lesbian and bisexual women were often considered inferior. Many doctors believe that lesbian and bisexual women can be identified by their physical appearance; they sometimes assume that lesbian and bisexual women are masculine in their presentation and behaviour.

As any woman who comes to a gynaecologist may be a lesbian or bisexual, the quality of the history taking, the development of rapport and the appropriateness of the advice given will be affected if her experiences, needs and specific fears are not understood. The good health practitioner is aware of the reasons why a lesbian or bisexual woman might be reluctant to seek health care, has an understanding of the effect of homophobia and heterosexism on health, and is knowledgeable about her specific health concerns. Lesbian and bisexual women often seek 'gay-friendly' health professionals, i.e. those who are non-judgemental in their attitudes, have an understanding of health needs and are able to facilitate the disclosure of sexuality (McNair 2003).

Assumption of heterosexuality

Unless a woman discloses, or 'comes out', to a healthcare professional, it is usually assumed that she is heterosexual. Some professionals may suppose that enquiry about sexual orientation is only relevant to the provision of health care if the concern specifically relates to sexual health. However, being a lesbian or bisexual woman is more than mere sexual behaviour. It may impact on the whole of a woman's social, family and personal life.

The issue of whether or not a lesbian or bisexual woman comes out to a gynaecologist or other health professional has consequences for her health. A number of health benefits may be associated with disclosure. Lesbian and bisexual women are likely to experience greater ease in communicating with their doctor and are more likely to be satisfied and comfortable with the care they receive if they have been able to come out and receive a positive response to their disclosure. Disclosure also allows for the possibility of involving their partner in treatment decisions. Non-disclosure may mean inaccurate diagnoses, inappropriate questioning and irrelevant health information.

The meanings about sexual behaviour differ from those for heterosexual women. The gynaecologist may need to know when the patient last had intercourse, or to advise her on resuming sex after surgery or the likely effects of treatment on sexual sensation or function. Healthcare professionals usually only understand heterosexual sex when they use the terms 'sex' or 'sexual intercourse'. If the gynaecologist regards every patient as heterosexual, the advice offered will reflect this assumption (e.g. the advice to avoid having sex with her husband). The presumption of heterosexuality is implicit when discussing whether a woman may be pregnant without realizing it, or in relation to advice offered about contraception.

Implications for Gynaecological Health

Reproductive health

Increasingly, lesbian and bisexual women are choosing to have children within same-sex relationships; this may be by home conception using sperm from a man who is known to

them, or through commercial networking agencies. Alternatively, they may choose to conceive at a licensed fertility clinic using a known sperm donor, or by using a sperm bank where the donor will remain anonymous to the mother (although the child may choose to know the identity of the father when they reach 18 years of age). If a woman is unable to conceive in these ways or has fertility problems, she may seek in-vitro fertilization (IVF) treatment.

A substantial amount of research exists about the parenting skills of lesbian couples. Research initially focused upon women who had started a family in a heterosexual relationship but who subsequently raised their children in a lesbian household. More recently, research has concentrated upon lesbian couples who seek to have a child through donor insemination at a licensed fertility clinic. Single women seeking fertility treatment with donor sperm have children who compare well emotionally and psychologically with children born by donor insemination to two heterosexual parents (Murray and Golombok 2005a,b). Social research on the children of lesbian parents has produced similar findings to those children born to single women. Their emotional and psychological development is comparable to that of children born of donor insemination to two heterosexual parents. In fact, the second female parent often has greater parent-child interaction than the father in heterosexual couples (Brewaey et al 1997).

Until the amendments to the Human Fertility and Embryology Bill in 2008, fertility clinics had an obligation not to provide treatment unless account had been taken 'of the welfare of any child who may be born as a result of treatment (including the need for a father)'. This was used by many to refuse treatment for lesbian couples; the wording has been replaced in the new legislation by the 'need for supportive parenting'. There has been a four-fold increase in the number of lesbian couples receiving IVF treatment (Human Fertilisation and Embryology Authority 2009). The implications for gynaecologists include: involving all parties desired by patients, including partners, known sperm donors and coparents; enabling women to make informed choices about interventions that are consistent with their known or presumed fertility; offering fertility support that is specific to lesbian and bisexual women; and helping lesbian and bisexual women to access other relevant services (Ross et al 2006). They also need to be aware of the known quality of lesbian parenting and be prepared to judge individual cases on the facts and evidence.

Lesbian mothers' access to maternity services

In the past, lesbian couples have been considered less ideal parents than their heterosexual counterparts. Their children were said to have difficulty forming a normal heterosexual identity. It was also assumed that children without a father lack appropriate gender role models; in particular, that a boy brought up by lesbians would be effeminate. Notwithstanding the obvious argument that most homosexuals were born to heterosexual parents (and thus the likely disconnection between the parent's sexuality and child's sexual orientation), and that most boys in single mother families remain heterosexual, empirical evidence is now available. Comparisons of children's development in lesbian mother and heterosexual households show no difference in the likelihood

of growing up gay; boys growing up in families without a father showed no less masculine gender role behaviour than boys brought up by a woman and a man (MacCallum and Golombok 2004).

Attitudes can influence how lesbian mothers are treated in maternity services (i.e. with hostility, curiosity or respect). Responses from healthcare professionals have sometimes been inappropriate, such as prying into a lesbian's decision to become a mother. In other circumstances, lesbians have felt that their partner was invisible or merely tolerated (Wilton and Kaufmann 2001). The changing social climate may mean that lesbian and bisexual women may be more likely to 'come out' to health professionals in the expectation that their relationship will be acknowledged, their partner will be treated as a coparent and their support needs, including referral to appropriate parenting support groups, will be met.

Cervical screening and cancer

As the risk of cervical cancer is associated with sex with men, lesbian and bisexual women are sometimes mistakenly believed to be at no risk or substantially lower risk of cervical cancer than heterosexual women (Fish 2009).

Studies suggest that up to four-fifths of lesbians have had sex with men in their lifetime (Marrazzo et al 2001). Human papillomavirus (HPV) has a long latency period (Carroll et al 1997), and any previous heterosexual sex may contribute to lesbians' risk of cervical cancer.

Smoking is also a risk factor for cervical cancer; there is some evidence that lesbians are more likely to smoke than heterosexual women (Gruskin et al 2001).

Transmission of human papilloma virus between women

Potential routes of transmission between women include oral sex, vaginal penetration with the fingers, sharing sex toys or skin-to-skin contact (Marrazzo et al 2001).

Prevalence of human papilloma virus and cervical cancer in lesbian and bisexual women

Researchers have sought to identify prevalence rates because no surveillance data are available on the incidence of cervical abnormalities in lesbian and bisexual women. A case-control study of 1408 lesbian and bisexual women and 1423 heterosexual women found that cervical abnormalities [cervical intraepithelial neoplasia (CIN) 1, CIN 2-3] were equally prevalent in both groups (Fethers et al 2000). A US clinic study reported a prevalence of HPV in lesbian and bisexual women of 13%; among those with HPV detected, 74% had oncogenic types (Marrazzo et al 2001).

Furthermore, cervical abnormalities have been found in women who report that they have never had sex with men (Bailey et al 2000, Fethers et al 2000, Marrazzo et al 2001). Lesbians whose female sexual partners have had previous heterosexual sex may therefore remain at some risk. Cervical abnormalities (borderline, mild, moderate or severe dyskaryosis) were more common in women who had been sexually active with men than in 'exclusively' lesbian subjects (10.9% vs 4.9%) (Bailey et al 2000).

Uptake of cervical screening among lesbian and bisexual women

Studies have found that lesbians, but not bisexual women, were less likely than heterosexual women to have been screened routinely (Diamant et al 2000, Matthews et al 2004, Kerker et al 2006).

Women's screening behaviour differed significantly according to whether they reported having had sex with men (Marrazzo et al 2001). Lesbians who had never had sex with men were more likely to report no prior screening than those who had been sexually active with men (42% vs 12%, $P < 0.001$, Bailey et al 2000).

Advice from healthcare professionals

There is evidence that lesbians are deemed to be ineligible for screening because of their sexuality; notwithstanding their risk from prior heterosexual sex, they are often judged on their current activities. Marrazzo et al (2001) found that 10% had been told by a healthcare provider that they did not need to be screened because they were not sexually active with men. These providers were identified as doctors in all but one case. There is also some evidence to suggest that lesbian and bisexual women have been refused cervical screening when they requested a test (Hunt and Fish 2008).

Sexually transmitted infections

Sex between women is often considered a negligible risk for sexually transmitted infections (STIs) (Mercer et al 2007). However, studies suggest that women who report that they have only had sex with women are susceptible; in woman-to-woman transmission, a greater number of sexual exposures are needed, while in heterosexual transmission, a greater number of partners increased the risk of transmission (Bauer and Welles 2001). STIs are more common among women who have had previous heterosexual contact or whose female partners have had male sexual partners (Carroll et al 1997, Mercer et al 2007). Bacterial vaginosis is more common among lesbians than among heterosexual women; it is significantly associated with a larger number of female sexual partners and smoking (Skinner et al 1996, McCaffrey et al 1999). Genital warts, genital herpes and trichomoniasis have been diagnosed in lesbian and bisexual women; other STIs such as chlamydia, pelvic inflammatory disease and gonorrhoea are comparatively rare (Bailey et al 2004). Gynaecologists and other healthcare professionals may need to consider the potential risks for STI transmission in medical decision-making. STI testing should be offered to lesbian and bisexual women based on the number and gender of their sexual partners (Bauer and Welles 2001).

Breast cancer

Lesbian and bisexual women are believed to be at higher 5-year and lifetime risk for breast cancer in comparison to heterosexual women; they are more likely to report a diagnosis of breast cancer than heterosexual women (Valanis et al 2000). Studies have suggested that reproductive factors may play a role, as they may have fewer pregnancies and children (Dibble et al 2004, Brandenburg et al 2007). Other potential risks include increased alcohol consumption, a

significantly greater number of breast biopsies and being overweight (Cochran et al 2001). Although the risks confuse behaviour (having children) with identity (being lesbian), some lesbians do have children while some heterosexual women do not; research suggests that the rates of nulliparity are higher among lesbians than heterosexual women (76% vs 22%) (Case et al 2004).

Breast awareness and screening behaviours

Key differences in breast health care between lesbians and heterosexual women may relate to breast awareness and screening behaviours. Despite controversy about the efficacy of breast self-examination, biomedical sources continue to advise women to be aware of changes in their breasts because as many as 90% of breast lumps are found by women themselves (Fish and Wilkinson 2003). Lesbians appear to be less likely to be 'breast-aware'; current health promotion emphasizes 'Touch, Look and Check'. Lesbians commonly said that they did not know what they were looking for or how to check their breasts (Fish and Wilkinson 2003). Although some studies find that lesbian and bisexual women attend for mammography at the same rates as heterosexual women (e.g. Fish and Anthony 2005), others suggest that relationships with health professionals and the anticipation of heterosexism may affect their experiences of mammography and their future reattendance (e.g. Lauver et al 1999).

Lesbian and Bisexual Women's Experiences of Health Care

The field of lesbian and bisexual women's experiences of health care is dominated by studies from North America and the quantitative research paradigm (Wilkinson 2002). Consequently, few studies have investigated sexual minority women's perceptions and experiences of health care. Recent government policy initiatives, the White Papers 'Choosing Health 2004' and 'Our Health, Our Care, Our Say 2006', seek to give patients greater choice about healthcare services and to consult with them about service delivery. There are a number of challenges, however, in eliciting the views of a hidden population. Although the following findings are derived from a non-random sampling survey, they represent the best-available data about lesbian and bisexual women's healthcare experiences in the UK (Hunt and Fish 2008). The questionnaire asked lesbian and bisexual women about how healthcare services can be improved. Analysis of the data identified three main themes: (i) assumption of heterosexuality, (ii) facilitating access and (iii) improving attitudes.

Assumption of heterosexuality

Although increasingly liberal social attitudes have meant that greater numbers of lesbian and bisexual women have 'come out' to their family, friends and work colleagues, health care is the environment where they are least likely to disclose their sexual orientation. Almost half of the lesbian and bisexual women in the study had not come out, or only to a few healthcare professionals (Hunt and Fish 2008). As one participant in the study said, receiving health care can

make a patient feel vulnerable, and additional barriers, such as coming out, may add to an already stressful situation:

Personally I have had very positive dealings with most GPs and hospital staff but there is this underlying assumption that when you bring your partner, you have either brought your sister or friend with you. Having to constantly out yourself to people who make this assumption, even when no malice is intended, is stressful when you're already in a stressful situation due to a health problem.

Some patients feel that they must make a choice between disclosing their sexual orientation or receiving a good service:

I have felt frightened in health care of having to choose between a good service and coming out [especially in hospital]. Healthcare providers need to show openly their welcome and skills for dealing with lesbian patients — posters, asking open questions, mentioning 'partners', not assuming sex of partner [or if they have a partner or just one partner], the usual things about not assuming you need contraception.

Healthcare professionals can take steps to make it easier for a lesbian or bisexual woman to disclose her sexual orientation and to understand the potential health benefits of doing so.

Facilitating access

Since the introduction of the Civil Partnership Act 2004, women in same-sex relationships have the same rights and responsibilities as married heterosexual couples, including the right in health care to have their partner recognized as their next of kin. The legislation has implications for all documentation where 'marital status' is required. Research undertaken by the Royal College of Nursing (2003) suggests that some healthcare professionals refuse to acknowledge a same-sex partner, and deny the partner visiting rights and access to information. Participants in the study shared similar experiences:

I feel that especially in hospitals, lesbian partners are not recognized immediately as next of kin and are subsequently overlooked and/or ignored when it comes to their spouse's treatment.

In contrast, other participants said that their relationship was acknowledged and that staff took steps to ensure that the patient could be visited by her partner without difficulty:

I had a protracted stay at a small rural hospital and had been nervous about how they would respond but in the end needed to come out to enable my partner access to my bedside. In fact we were very pleasantly surprised and staff made a conscious effort, handing over to new staff each shift that my partner was female and should be allowed to visit, thus preventing any difficulties/awkwardness.

Access to health care can also be facilitated by positive images, relevant health promotion materials, clearly dis-

played confidentiality policies and equal opportunity policies which include sexual orientation.

Improving attitudes and behaviours

The doctor-patient relationship is often said to be as important to a patient's experience as the treatment of disease (Wilton 2000). Skilled interviewing and positive attitudes are associated with good health care; doctors' values and attitudes are linked to patient satisfaction, the willingness of a patient to return to their health provider and improved health outcomes (Gruskin 1999). Attitudes are also informed by knowledge about lesbian and bisexual women's communities and the ways in which their lives are organized:

For the most part, my experience and my partner's experience have been extremely positive and we have generally encountered excellent care from healthcare professionals. However, it was really a problem for us, and more particularly for our children's father, that our local hospital was unable to accommodate our unusual family structure during the births of our children.

Conversely, poor attitudes have a potentially detrimental impact on health care:

During a visit to [unnamed] Hospital in London for a gynaecological problem, the nurses were surprised to find out that I had two children. Health professionals must think I'm from another planet just because I'm a lesbian. It's a real shame that their experience of our community is still so very limited.

Education and Research

Undergraduate medical education

Studies point to the absence of lesbian and bisexual women's health concerns on undergraduate and postqualifying medical curricula, and highlight the need for cultural competence, including sensitive communication and informed values (Hutchinson et al 2006).

Research in lesbian and bisexual women's health

Unlike for heterosexual women, research in lesbian and bisexual women's health has been largely overlooked. A review of English language articles found that only 0.1% ($n = 3777$) of all articles cited in Medline addressed lesbian, gay, bisexual or transgender issues (Boehmer 2002). Almost two-thirds (61%) of these were disease specific, pointing to the continuing dominance of the biomedical paradigm, and most (80%) focused on gay men. These findings suggest that lesbian and bisexual women's concerns have been historically neglected in health research. In recent years, the research base has grown in the USA and this can be attributed to a number of factors, including increased access to research funding, the establishment of a lesbian health fund by the Gay and Lesbian Medical Association, the development of new methodologies in lesbian and bisexual women's health, and the inclusion of questions relevant to

sexual minority women on population-based studies (Solarz 1999). However, there are continuing obstacles: research grants are relatively small, there are few available funding streams, and significant barriers to publication remain (Plumb 2001).

Towards Good Practice

This section identifies a number of pointers for good practice which can be incorporated into everyday healthcare interactions. What would a good gynaecologist provide for his or her lesbian patients?

Knowledge

Good gynaecologists provide high-quality, skilled medical care for all their patients, regardless of background. The well-trained gynaecologist would have awareness that any patient who attends (single, married, young, old, White or Black) might be lesbian or bisexual, and would not make assumptions on the basis of appearance or probability. He or she would be apprised of the health risks and health concerns that different sexual behaviours and identity might bring.

Having knowledge of appropriate services, support groups and referral networks would allow consultations to take place freely, as the doctor would be confident to cope with disclosure, distress or expectations of help.

Professionals need to be sensitive to historical stigmatization, and it is particularly important to understand the need for confidentiality when 'coming out' might be dangerous to self-esteem, family relationships or security at work.

A lesbian might have 'next of kin' issues in that her biological family and social network of good friends and support may be fully integrated or estranged, and this requires sensitivity, especially around visiting time and discussions about competence or end-of-life.

Communication skills

It is not very difficult to create a 'trusting' or 'distrusting' atmosphere with patients. Simple things, such as posters in the waiting room, wearing of lapel pins or badges, family photos in the surgery and the use of language, can create a very welcoming or potentially hostile environment even before a consultation starts. Contrary to popular belief, you cannot tell if a woman is a lesbian or bisexual from her appearance, but only if she tells you; this will be dependent on her working out what your reaction might be.

Questions that use inclusive terms will facilitate safe disclosure. Gender-neutral language such as 'Who do you live with? Have you a partner? Does he or she work', rather than 'What work does your husband do? Are you using contraception? Why not?', are more likely to put lesbian or bisexual patients at ease.

Attitudes

Good doctors, even those who have deep seated religious, political or personal beliefs that might conflict with their

patients' beliefs or lifestyles were they to meet in a non-professional context, will put those aside in the consulting room as they recognize that prejudice will hamper their ability to do their best for all patients. An awareness of heterosexism and homophobia in health care and in everyday life would allow the doctor to empathize ('walk in another's shoes'), be non-judgemental and avoid stereotypes about lesbians (e.g. that they are all 'mannish' or 'man-haters'). Just as with heterosexuals, it is important to assess the quality of their social support and relationships, and preferably involve partners in treatment decisions.

Conclusions

Recommendations

Lesbian and bisexual women's health should be included in medical education programmes

The curriculum should include: (i) training in lesbian and bisexual women's needs and risks, and (ii) training in cultural competence by displaying the attitudes and values to promote health and wellbeing through appropriate communication with lesbian and bisexual women, taking sensitive sexual histories, and knowledge and understanding of sexual minority women's health concerns.

Avoid assumptions of heterosexuality

Healthcare professionals should take steps to facilitate disclosure, to ask questions in ways which do not presume heterosexuality and to understand differences in meanings (e.g. when referring to sexual activity). However, not all lesbian and bisexual women will choose to come out to their doctor.

Develop a welcoming environment

Reception staff should develop cultural competence; clinic waiting rooms should have written policies on sexual orientation antidiscrimination, clear confidentiality policies and relevant intake forms; and posters, brochures and other health promotion materials should be displayed or made available.

Competent gynaecologists will:

- be aware that any patient might be lesbian or bisexual, and will not make assumptions on the basis of appearance or probability;
- be aware of sexual orientation as a social determinant of health;
- be knowledgeable about the different health risks and health behaviours affecting sexual minority women;
- be aware of appropriate referral networks;
- be willing to facilitate the disclosure of sexual orientation by the use of inclusive terms such as 'partner';
- involve partners and/or friends as next of kin in medical decision-making; and
- facilitate access to health care by positive images, relevant health promotion materials, clearly displayed confidentiality policies and equal opportunity policies which include sexual orientation.

KEY POINTS

1. Any patient might be lesbian or bisexual.
2. Gynaecologists should not make assumptions on the basis of appearance or probability.
3. Sexual orientation is a social determinant of health.
4. There are some different reproductive health risks and health behaviours affecting sexual minority women.
5. Gynaecologists should be: (i) willing to facilitate the disclosure of sexual orientation by the use of inclusive terms such as 'partner'; (ii) willing to involve partners and/or friends as next of kin in medical decision-making; and (iii) be aware of appropriate referral networks. Access to health care is facilitated by positive images, relevant health promotion materials, clearly displayed confidentiality policies and equal opportunity policies which include sexual orientation

Acknowledgement

The authors wish to acknowledge the late Tamsin Wilton's contribution to the development of lesbian health as a research discipline, and to her particular influence in the writing of this chapter.

Evidence-based care in gynaecology

INTRODUCTION	1017	CONCLUSION	1024
EVIDENCE-BASED MEDICINE PROCESSES	1017	KEY POINTS	1024

Introduction

Evidence-based medicine (EBM) has been defined as the 'conscientious, explicit and judicious use of current best evidence in making decisions about the care of individual patients' (Sackett et al 1996). It incorporates three fundamental elements: external research evidence, clinical expertise, and patients' views and values in the delivery of health care (Figure 68.1).

Although discussions about EBM generally revolve around acquisition and appraisal of external research evidence, the critical importance of the other two components cannot be overstated. Failure to elicit the right diagnosis or to communicate the management plan to a patient in a meaningful way is unlikely to lead to better clinical outcomes. Similarly, if a patient's beliefs, expectations and concerns are not explored and incorporated into the management plan, a well-laid-out course of therapy may fail due to lack of compliance. The ideal clinical decision is a product of complex personal characteristics as well as objective research evidence. Effective implementation of EBM is only possible if a proposed intervention has the support of health professionals and patients.

The aim of this chapter is to introduce the reader to the concept of EBM as applied to clinical gynaecology.

Evidence-Based Medicine Processes

The practice of EBM involves systematically identifying, appraising and applying contemporaneous research findings as the basis of clinical decisions. This process is often summarized by the four 'A's:

- Ask: formulate a structured question based on a clinical problem.
- Acquire: search the literature for relevant guidelines, reviews or primary article(s).

- Appraise: evaluate (critically appraise) the literature for validity and usefulness.
- Apply: implement useful relevant research findings in clinical practice, taking patient preferences into account.

A fifth 'A' for 'Audit' can be added to these steps to take EBM beyond the care of the individual patient (Figure 68.2).

Formulation of a structured question

A well-structured question is essential in order to get the right clinical answer. It also facilitates the process of searching for evidence. A suggested approach uses five components (PICOD: Population, Intervention, Comparison, Outcome(s) and Design), as shown in Table 68.1.

The purpose of this step is to get clarity regarding the clinical question. Writing down the question in free form often makes it possible to break it down into a PICOD format. In practice, this may not always be feasible for all clinical questions, and missing out some elements of PICOD is not necessarily a cause for concern.

Searching the literature

Approximately 17,000 journals collectively publish over 1 million biomedical articles each year. Identifying relevant articles will require the use of apposite keywords (and their combinations) to search appropriate databases. A hierarchical approach to literature searching is recommended (Figure 68.3).

The first step is to look for an up-to-date professional guideline that has been developed on the basis of systematic appraisal of available evidence. Table 68.2 lists some sources of guidelines and evidence summaries. The Royal College of Obstetricians and Gynaecologists (RCOG) has long acknowledged the need to update clinical practice on the basis of research findings. Since 1973, the RCOG has

Figure 68.1 Evidence-based medicine (EBM) triad: the three components of EBM.

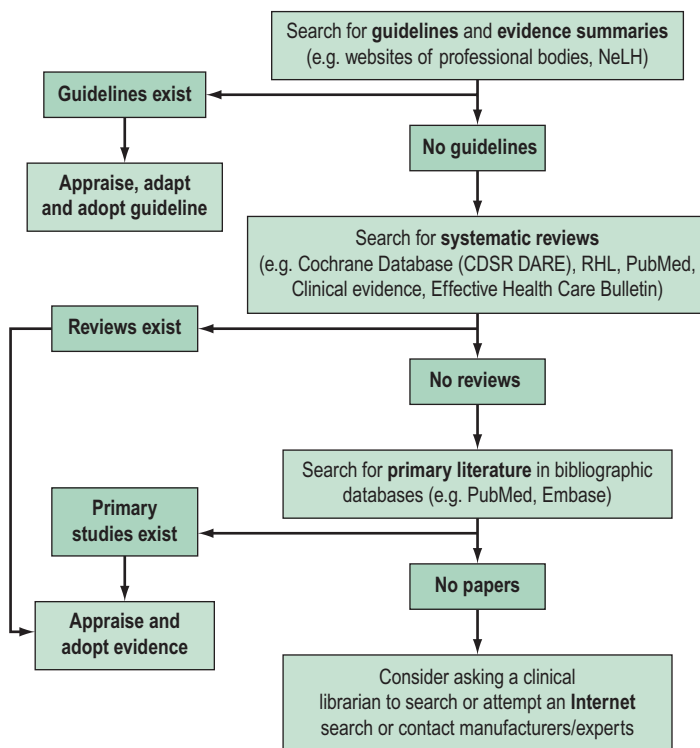

Figure 68.2 The five 'A's of evidence-based medicine.

regularly convened study groups to address important growth areas within the specialty. These groups have met, evaluated the results of research and conducted in-depth discussions on a variety of topics. These discussions have shaped the development of clinical recommendations which were initially based on consensus. Over the years, this approach has been modified in order to produce genuine evidence-based guidelines. To be effective and relevant,

Table 68.1 Components of structured clinical questions

Component	Example 1	Example 2
P: Population, patient or problem	In women suffering with heavy menstrual bleeding...	In postoperative women with swollen legs...
I: Intervention (test, medical or surgical treatment, or process of care)	... would treatment with norethisterone...	... would a Doppler ultrasound be accurate...
C: Comparison (placebo, another alternative treatment or the gold standard in a diagnostic accuracy study)	... compared with no treatment at all or alternative treatments (e.g. levonorgestrel IUS)...	... compared with venography as the gold standard...
O: Outcome(s)	... lead to an improvement in their symptoms?	... in diagnosing deep venous thrombosis?
D: Ideal design for the study	A randomized controlled trial	A test accuracy study

IUS, intrauterine system. Produced by Bob Phillips, Chris Ball, Dave Sackett, Doug Badenoch, Sharon Straus, Brian Haynes, Martin Dawes since November 1998. Updated by Jeremy Howick March 2009.

guidelines must fulfil the following three essential criteria.

- They must be multidisciplinary: in other words, they must be developed by a multiprofessional working group including clinicians, nurses and other health professionals as well as users of health services (i.e. consumer representatives).

- They must be evidence based: guideline development must include a systematic search for and synthesis of all available research evidence.
- They must be evidence linked: individual recommendations within a guideline must be explicitly linked to the strength and quality of the evidence on which they are based, using a recognized grading scheme (Centre for Evidence-based Medicine, Oxford University, www.cebm.net) (see Appendix).

It is generally anticipated that national guidelines will, in turn, be used as a basis for the development of local protocols and guidelines in conjunction with local commissioners and providers of health care as well as service users. These

should take into account the specific needs of local service provision and the preferences of the local population.

In the absence of credible evidence-based guidelines, the next step would be to search for an up-to-date, good-quality, systematic review. Some sources of systematic reviews are given in Table 68.3.

Apart from the traditional sources of systematic reviews, such as the Cochrane Library and DARE, MEDLINE and Pubmed have now become a rich source of systematic reviews. Pubmed contains a systematic review filter within Pubmed Clinical Queries (<http://www.ncbi.nlm.nih.gov/entrez/query/static/clinical.shtml>), and MEDLINE has the indexing term 'reviews, systematic' as a 'publication type'.

If no systematic reviews are identified, or if reviews are out-of-date, non-systematic or of marginal relevance to the clinical question, it is necessary to continue the literature search for primary studies. Table 68.3 provides a list of important sources of primary literature.

Efficient searching for primary literature requires training and practice, and input from an experienced librarian or

information scientist. Careful selection of keywords for searching, matching these keywords to Medical Subject Heading terms, and combining the terms with 'AND' or 'OR' Boolean operators are necessary skills that are best learnt from librarians. Pubmed carries three tools that clinicians can employ to optimize their searches, and these are discussed below.

Pubmed 'clinical queries' (www.ncbi.nlm.nih.gov/entrez/query/static/clinical.shtml)

This has now established itself as the primary gateway for efficient literature searching to support evidence-based practice. 'Clinical queries' uses filters that allow retrieval of articles for the five main categories of clinical questions: therapy, diagnosis, aetiology, prognosis and clinical prediction. The option of 'sensitive search' in 'clinical queries' allows for a broad search that may identify many relevant articles, but also carries the risk of getting many irrelevant hits; the 'specific search', on the other hand, performs a narrow search and would retrieve fewer articles, but at the risk of missing some relevant articles. It is advisable to start with a sensitive search, and to move to a specific search if the number of hits is unmanageably large on the sensitive search.

Pubmed 'SLIM' (SLider Interface for Medline/Pubmed)

This exciting new development uses six different slider bars to control search variables, improving user control and the capability to instantly refine and refocus search strategies (<https://pmi.nlm.nih.gov/slim/>).

Pubmed 'related articles'

Once a relevant citation is found, clicking on the 'related articles' function to the right of the identified citation retrieves other similar articles.

Evaluation of the literature

Once relevant articles have been identified and retrieved, the next step is to select those which are appropriate and methodologically sound. Many papers published in medical journals have serious design flaws, and most are irrelevant for everyday clinical practice. Most clinicians are accustomed to functioning as 'users' when dealing with evidence to support practice, but the absence of up-to-date and valid preappraised evidence makes it necessary to switch to an 'appraiser' mode and evaluate articles in terms of validity (methodological soundness), importance {e.g. effect sizes [relative risks, odds ratio, numbers needed to treat (NNT) for therapy studies, and accuracy estimates (e.g. likelihood ratios)] for test accuracy studies}, and applicability of the results in practice.

In addition, an overall judgement on the quality of the evidence will need to take two other issues into account: consistency, the extent to which different studies found similar results; and robustness, the extent to which minor alterations in results do not change the conclusions drawn from those data.

Various checklists can be used to appraise different types of clinical questions. Checklists for therapeutic and diagnos-

Table 68.4 Research designs for specific clinical questions

Clinical question	Ideal research design
Effectiveness of therapy	RCT
Prevention	RCT
Screening	Cluster RCT
Diagnosis (accuracy)	Cross-sectional study (comparison of index test with reference standard test)
Prognosis	Cohort study
Aetiology	Case-control or cohort study
Adverse events	Case report, case series, case-control studies, cohort studies and RCTs
Economic assessment of medical interventions	Depending on the exact question: Cost-minimization study Cost-effectiveness study Cost-utility study Cost-benefit study
RCT, randomized controlled trial.	

tic questions as well as systematic reviews are given in Tables 68.5, 68.7 and 68.10. In appraising a study, it is important to assess the suitability of the research design and methods used in the context of the specific clinical question. Randomized trials provide the best evidence for treatment, but valid evidence for diagnosis, prognosis and causation may be derived from publications based on other study designs (Table 68.4).

Appraising a paper on effectiveness of therapy (randomized controlled trial)

A randomized controlled trial reduces the risk of bias (systematic deviations or errors in the results) by minimizing the likelihood of important differences between the treatment and control arms of the study. If no randomized controlled trials are available, other research designs (e.g. a non-randomized controlled study or even a case-control study) may provide valuable information about therapy, although they may exaggerate the potential benefits of treatment and thus represent a lower grade of evidence (see evidence grades, Centre for Evidence-based Medicine, Oxford University, www.cebm.net) (see Appendix). A checklist can be used to appraise a therapy article (Table 68.5).

If the results for a randomized controlled trial are dichotomous (i.e. a 'yes/no' outcome), and there are two arms in the study, the findings can be presented and analysed in a 2×2 table, as shown in Table 68.6.

NNT is a particularly useful measure to express the magnitude of treatment benefit. NNT is defined as the number of patients that will need to be treated to achieve one additional good outcome. Thus, the lower the NNT, the greater the magnitude of the outcome, and an NNT below 10 is often (arbitrarily) regarded as a 'large effect size'. However, such arbitrary thresholds for defining benefit sizes should be used with caution, as a small effect size (with a correspondingly large NNT) can still be important if the outcome in question is serious (e.g. deaths prevented).

Table 68.5 Critical appraisal checklist for randomized controlled trials**I. Are the results valid?**

1. Is the assignment of patients randomized? Appropriate methods are: random number tables and computer-generated random numbers
2. Is allocation of treatment concealed? Appropriate methods are: opaque envelopes, third party randomization, distant (telephone or Internet) allocation
3. Are patients, health workers and study personnel 'blinded' to the intervention?
4. Are patients analysed in the groups to which they were randomized? ('intention to treat' analysis)
5. Are all patients who entered the trial properly accounted for?
6. Is follow-up complete?
7. Are the randomized groups similar at the start of the trial? (normally presented in 'Table 1' of the article)
8. Apart from the experimental and control interventions, are the groups treated equally?
9. Was the study adequately powered?*
10. Was ethical approval obtained for the study?*

II. What are the results (i.e. importance of results)?

1. How large is the treatment effect? (reported as relative risks, odds ratios, absolute risks, numbers needed to treat or differences in means or medians)
2. How precise is the treatment effect? (95% confidence intervals around the above)

III. Will the results help me in caring for my patients (applicability)?

1. Can the results be applied to my patients?
2. Are all clinically important outcomes considered?
3. What are the likely benefits? Are they worth the potential harms and costs?

*These items do not strictly relate to 'validity'; nevertheless, they are important and should be part of the appraisal process.

Table 68.6 2 × 2 table to present the results of a two-arm trial with a dichotomous outcome

	Outcome (live birth)	
	Event	Non-event
Experimental group (surgery for endometriosis)	a	b
Control group (no surgery)	c	d

Risk in the experimental group (or experimental event rate) = $a/(a+b)$
 Risk in the control group (or control event rate) = $c/(c+d)$
 Relative risk (or risk ratio) = $[a/(a+b)]/[c/(c+d)]$
 Absolute risk reduction (ARR) = $[c/(c+d)] - [a/(a+b)]$
 Numbers needed to treat = $1/ARR$
 Odds in the experimental group = a/b
 Odds in the control group = c/d
 Odds ratio = $(a/b)/(c/d)$

Appraising a diagnostic article

The checklist shown in Table 68.7 can be used to appraise a diagnostic accuracy article. It should be noted that this checklist only applies to accuracy studies; there are other aspects of testing that may need to be judged on other crite-

Table 68.7 Critical appraisal checklist for diagnostic accuracy studies**I. Are the results valid?**

1. Does the patient sample include an appropriate spectrum of patients to whom the test will be applied in clinical practice?
2. Are the test and reference (gold) standard results blinded?
3. Did everyone get both the test and the reference standard?
4. Is the test described fully?
5. Is the reference standard described fully?

II. What are the results?

1. What are the results? (sensitivity, specificity, predictive values or likelihood ratios)
2. What is their precision? (95% confidence intervals)

III. Will the results help me in caring for my patients?

1. Are the results applicable to my patients?
2. Will the results change my management?
3. Will patients be better off as a result of the test?

ria. For example, evaluating the inter- or intraobserver reliability or the clinical impact of testing will require designs other than the one employed for accuracy evaluation, and will often need to be judged by other criteria.

The sensitivity, specificity, predictive values and prevalence are defined in the marginal cells of Table 68.8. The sensitivities and specificities are often misinterpreted, and the mnemonics 'SnNout' and 'SpPin' are very useful to ensure correct interpretations.

- SnNout: when a test has high Sensitivity, a Negative test result rules *out* the diagnosis.
- SpPin: when a test has high Specificity, a Positive test result rules *in* diagnosis.

Thus, sensitivities relate to negative test results, whilst specificities relate to positive test results.

Likelihood ratios, which can be calculated from the 2 × 2 table, or derived from sensitivities and specificities as shown in the footnote of Table 68.8, are generally considered to be the most useful of all test accuracy summaries. The likelihood ratio indicates how much a given test result raises or lowers the probability of having the disease. The higher the likelihood ratio of an abnormal test, the greater the value of the test. Conversely, the lower the likelihood ratio of a normal test, the greater the value of the test. Although a guide to the interpretation of likelihood ratios is provided in Table 68.9, it should be noted that the value of a test may vary depending on the pretest probability and the consequences of having the condition.

Appraising a systematic reviews or meta-analysis

A systematic review aims to provide a complete exploration of evidence on a subject. It is an overview of studies using explicit, systematic and therefore reproducible methods to locate, select, appraise and synthesize relevant and reliable evidence. Although the terms 'systematic review' and 'meta-analysis' are often used interchangeably, the term 'meta-analysis' has a specific meaning; it is the mathematical pooling of numerical results from individual studies. All good systematic reviews have the following five features:

Table 68.8 2 × 2 table for test accuracy results

Reference standard (e.g. venography to confirm or refute the diagnosis of DVT)				
Index test (e.g. ultrasound Doppler to diagnose DVT)		Disease present	Disease absent	
	Positive test	a (true positive)	b (false positive)	PPV = $a/(a+b)$
	Negative test	c (false negative)	d (true negative)	NPV = $d/(c+d)$
		Sensitivity = $a/(a+c)$	Specificity = $d/(b+d)$	Prevalence = $(a+c)/(a+b+c+d)$

DVT, deep venous thrombosis; PPV, positive predictive value; NPV, negative predictive value.
 Likelihood ratio for positive test (LR+) = $[a/(a+c)]/[b/(b+d)]$ = sensitivity/(1 – specificity)
 Likelihood ratio for negative test (LR–) = $[c/(a+c)]/[d/(b+d)]$ = (1 – sensitivity)/specificity

Table 68.9 Interpretation of likelihood ratios (LR)

LR for positive test	LR for negative test	Value of test
>10	<0.1	Very useful
5–10	0.1–0.2	Moderately useful
2–5	0.5–0.2	Somewhat useful
>1–2	0.5–<1	Little useful
1	1	Useless

- a clearly framed question;
- comprehensive literature search across multiple databases for published and often unpublished data;
- explicit inclusion and exclusion criteria for study selection;
- careful assessment of methodological quality of the included studies; and
- synthesis of the evidence (with quantitative synthesis, or meta-analysis when appropriate).

The checklist in Table 68.10 can be used to appraise a systematic review.

One needs to be mindful of the following three issues when interpreting the findings of systematic reviews and meta-analyses.

- ‘Garbage in, garbage out’: if the studies that make up a systematic review are flawed, the systematic review itself is likely to be unreliable.
- Publication bias: unfortunately, studies that show negative and/or statistically non-significant results are less likely to be published. This could be due to apathy or conflict of interest of the researchers or sponsors, or the disinterest of journal reviewers and editors. Although systematic reviewers are expected to make all efforts to locate published and unpublished data, it is possible that negative studies remain buried, thus biasing the findings of a review. Statistical tests such as funnel plot analysis can indicate the presence of publication and related biases.
- Heterogeneity: the degree to which the effect sizes from the various individual studies in a systematic review agree (homogeneity) or disagree (heterogeneity) has important implications for inferences. If the findings

Table 68.10 Critical appraisal of systematic reviews

I. Are the results valid?

1. Does the article address a clearly focused question? (i.e. are the PICOD elements defined clearly?)
2. Are the criteria used to select articles for inclusion appropriate?
3. Is the literature search comprehensive? (MEDLINE, EMBASE, Cochrane Library, CINAHL, searchers for abstracts, hand-searching etc.)
4. Is the validity of the included studies appraised? (using checklists or tables like those given in Tables 68.7 and 68.9)
5. Did two or more reviewers extract the data independently?
6. Are the results consistent from study to study?
7. Is there an assessment for publication bias? (e.g. funnel plot analysis)

II. What are the results?

1. What are the results of the study?
2. How precise are the results? (95% confidence intervals)

III. Will the results help me in caring for my patients?

1. Can the results be applied to my patient care?
2. Are all clinically relevant outcomes considered?
3. Are the benefits worth the harms and costs?

are homogeneous (i.e. the results of various studies agree with each other), one is more likely to believe the meta-analysed summary result. Heterogeneity can be assessed visually by examining the forest plot, or statistically using tests such as Chi-square, Cochran Q or I^2 statistics.

Findings of a meta-analysis are often presented as a forest plot (Figure 68.4). Forest plots can be used to plot relative risks, risk differences, odds ratios, mean differences or other summary estimates such as sensitivities, specificities and likelihood ratios. Each individual study in the systematic review is represented in a row, with its own point estimate (the ‘box’) and the 95% confidence interval (the ‘whiskers’). The pooled summary estimate is shown as a diamond at the bottom of the chart. The centre of the diamond represents the pooled estimate and the ends of the diamond represent the 95% confidence interval for the pooled estimate.

Implementation of useful findings

The final step in EBM is implementation or incorporating the identified evidence in clinical practice. This may seem a

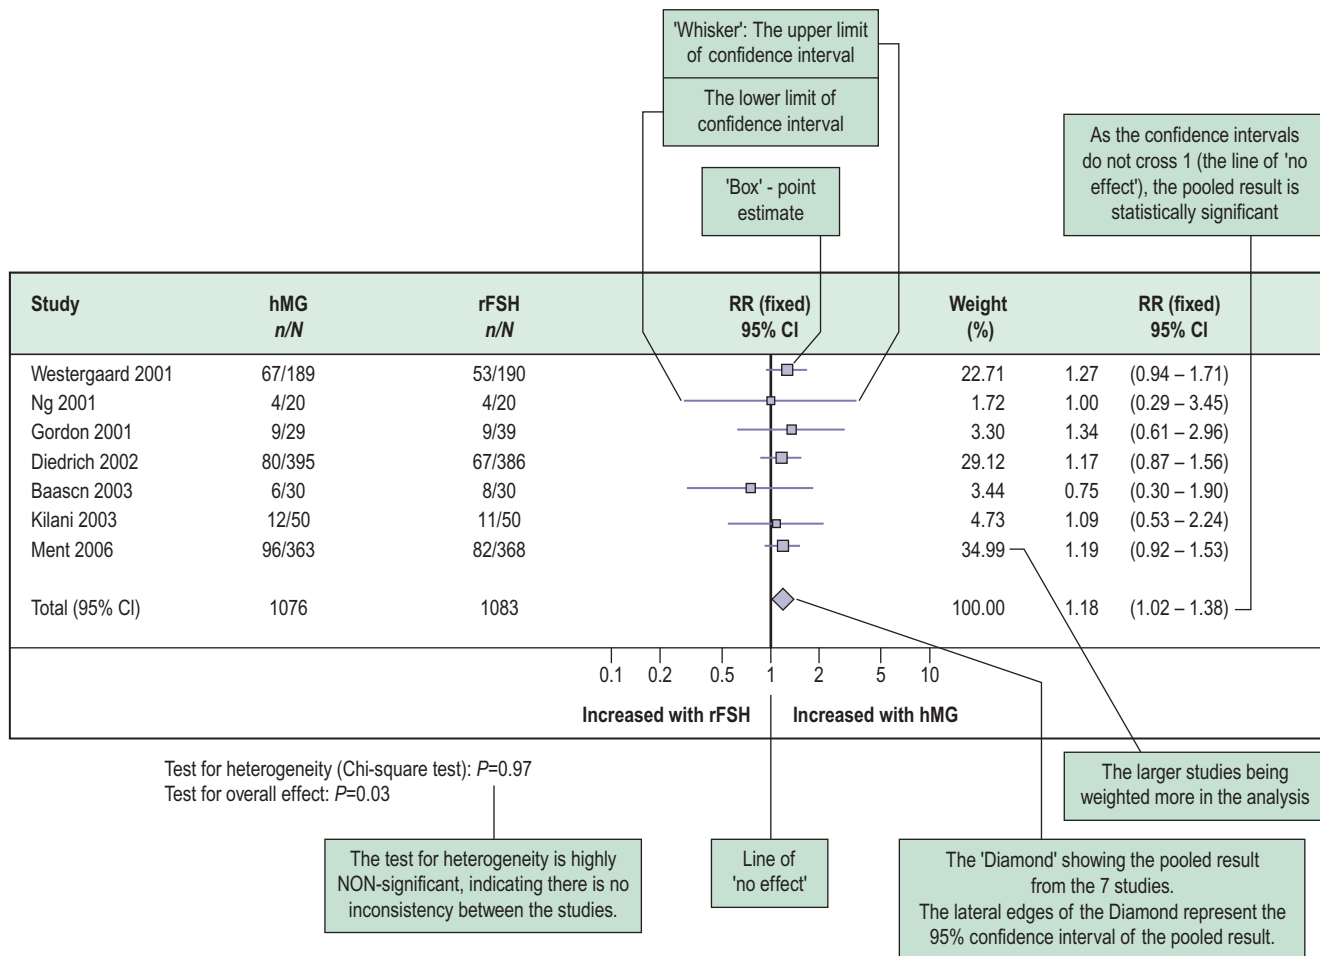

Figure 68.4 An example of a forest plot: urinary human menopausal gonadotrophin (hMG) versus recombinant follicle-stimulating hormone (rFSH) for controlled ovarian hyperstimulation in in-vitro fertilization (IVF) treatment for the outcome of live births per IVF cycle started. RR, relative risk. See the source reference for details of the individual study references.

Source: Coomarasamy A, Afnan M, Cheema D, van der Veen F, Bossuyt PM, van Wely M. Urinary hMG versus recombinant FSH for controlled ovarian hyperstimulation following an agonist long down-regulation protocol in IVF or ICSI treatment: a systematic review and meta-analysis. *Hum Reprod.* 2008 Feb;23(2):310–5.

deceptively simple step (e.g. a case of writing up a prescription), but in practice can be the most complex of all EBM steps. As a minimum, this requires careful consideration of the following issues.

How generalizable are the results of the study to your specific patient or patient group?

This issue is variously described as 'generalizability', 'applicability' or 'external validity', and requires the examination of study population (e.g. the inclusion and exclusion criteria) and study conduct to answer the question: 'Are there important reasons to believe that the results of this study may not apply to my patient(s)?' It is important not to be unreasonably stringent in this evaluation. For instance, if a US study recruiting women under the age of 40 years with severe endometriosis found that treatment X was effective in improving quality of life, would the evidence apply to a 42-year-old English woman with moderate endometriosis? Although this woman may not have been eligible for the trial, there is probably no reason to believe that the results of the study should not apply to her.

What is the balance between benefit and harm?

Many effective treatments come with their own set of problems, including adverse effects, toxicity and operative complications (for surgical interventions). Whilst a full and formal clinical decision analysis or other similar techniques to comprehensively analyse the net benefits and harm with their associated values and costs would be outside the scope (and perhaps need) of most clinicians and their patients, it is essential that an overall assessment of the net balance sheet is made. To make a reliable assessment on this issue, the identified studies need to have reported all clinically relevant outcomes over a reasonable period of time. Often, it is necessary to undertake separate literature searches to identify rarer or long-term adverse outcomes.

What does the patient think?

Eliciting ideas, concerns and expectations from the patient about the condition and the potential therapeutic interventions that are available is crucial to a successful consultation. Patients may place different values on various outcomes and adverse events; unless these are elicited and incorporated

into the decision-making, satisfaction with the management plan and compliance with therapy are unlikely to ensue. Building a partnership with the patient, providing a balanced discussion about the risks and benefits, and seeking agreement and providing support are all essential to the 'Apply' step of EBM.

Despite being accessed and appraised systematically, most research findings are currently applied intuitively. If EBM is to be seen through to its logical conclusion involving a synthesis of empirical evidence and human values, the current conflict between the explicit collection of data and its implicit use must be addressed. This area is being investigated and possible options are being evaluated. These include decision analysis, which provides an intellectual framework for the development of an explicit decision-making algorithm (Lilford et al 1998), and computerized decision support systems. When there are several treatment options which may have different effects on a patient's life, there is a strong case for offering patients a number of choices. It is possible that their active involvement in the decision-making process

may actually increase the effectiveness of the treatment (Coulter et al 1999).

Conclusion

The purpose of clinical research is to generate new knowledge on how to treat individual patients and how best to deliver healthcare services. The objective of EBM and its component activities is to maximize the extent to which clinical practice is based on research evidence, and consequently improve the net health gain for patients. Within gynaecology, the recent years have seen considerable progress in strategies aimed at seeking, appraising and applying evidence. A comprehensive approach towards getting research evidence into practice is promoted by National Health Service clinical effectiveness and clinical governance initiatives. What is being challenged is the way in which doctors make clinical decisions and the way in which patients respond to them.

KEY POINTS

1. Evidence-based medicine (EBM) involves the integration of best available research evidence with clinical expertise and patients' views and preferences.
2. EBM has four steps: (i) Ask a structured clinical question; (ii) Acquire the relevant literature; (iii) Appraise the literature for validity and usefulness; and (iv) Apply the findings.
3. Asking a structured clinical question involves breaking it down to PICOD: Population, Intervention, Comparison, Outcomes, and Desired study design.
4. Acquiring evidence involves taking a hierarchic approach to literature searching: look for evidence-based guidelines first, then for systematic reviews, and then for primary studies if no relevant guidelines or systematic reviews exist.
5. Good guidelines are evidence-based, evidence-linked and produced by a multidisciplinary team. They can often be found in various professional body websites.
6. Appraisal of literature involves assessment for validity, usefulness and applicability.
7. Strategies need to be developed to overcome existing barriers to the wider implementation of evidence-based care in gynaecology.
